Even if plasmids do not exactly fit the bill as model bacterial chromosomes, the research in plasmid has been rewarding in revealing several new regulatory principles. The first and foremost is the seminal discovery of regulation by antisense RNA (Sect. 2.1.2). Other novel mechanisms include initiator inactivation by a covalent DNA adduct (Sect. 2.1), gene silencing by spreading of a site-specific DNA-binding to flanking DNA (Sect. 2.2), microtubule-like

polymer formation in bacteria (Sect. 2.2), pole-to-pole oscillation of a partition protein in plasmid segregation (Sect. 2.2), plasmid addiction by toxin–antitdote gene pair (Sect. 2.3), and plasmid multimerization dependent gene expression of *rcd* (Sect.2.4). One can also consider the elucidation of the steps of maturation of *hok* RNA as an outstanding achievement (Sect. 2.3.1).

4.3 Future Potential

The boundary between chromosome and plasmid has become fuzzier with the discovery of chromosome-size megaplasmids such as pSym plasmids of *Shinorhizobium meliloti*, distribution of genome into multiple genetic elements as in *Borellia*, and ever-increasing discovery of plasmid genes in chromosomes. The new realization of the impact of plasmids on bacterial evolution has made understanding of plasmid behavior particularly in the environment all the more necessary. Little is known about how cells communicate and prepare themselves for conjugative plasmid transfer. BHR plasmids are particularly powerful to study adaptation at the molecular level. Plasmids will remain attractive and convenient systems to study how genes are counted, their fluctuations are adjusted, how they are sorted, and how they migrate intra- and extracellularly. Much of these processes need to be understood quantitatively and in kinetic terms. The present day technologies are allowing single cell and even single molecule measurements. These are welcome developments as steady state measurement is an imperfect proxy to understand control processes. If past performance is any guide, a wealth of new knowledge remains to be gained by studying existing plasmids in greater depth in the laboratory and in their natural niche, and studying new plasmids from exotic habitats.

Keywords

k-GRAM (k-tuple)
String (sequence) of k symbols chosen from a given elementary alphabet. In the case of nucleotide sequences, k-grams correspond to oligonucleotides of length k. The most frequently used nucleic acids elementary alphabet is {A, C, G, T (or U)}, where letters stand for adenine, cytosine, guanine, and thymine (or uracil) nucleotides respectively. Other alphabets used in nucleic acids studies include: {K, M}, where K is either guanine or thymine (uracil in RNA) and M is either adenine or cytosine; {R, Y} where R is a purine (adenine or guanine) and Y is pyrimidine (either cytosine or thymine); {S, W} where S is either cytosine or guanine and W is either adenine or thymine (or uracil in RNA).
If the elementary alphabet contains n symbols and k is fixed, we refer to a set of all n^k k-grams as *k-gram* (nonelementary) *alphabet*.

Pattern
There is no general definition of pattern. It can be any logical, geometrical or (broadly) factual connection between elements of a model that attracts our attention. ''Pattern'' is usually understood ostensively by experienced explorers of the same model.

Motif
Motif (sequence motif) is a term used in sequence analysis to refer to detectable and stable feature that can be used to characterize a conserved meaningful function or structure. There are several different specific meanings of ''motif,'' which depend on the subject matter (specific function or structure) to which they are applied. Most frequently used definitions of the word ''motif'' in biomolecular sequence analysis include the following:

1. Motif is a string or regular expression that significantly often occurs in a collection of similar sequences. Vast majority of ''motifs'' discussed in molecular biology literature are ''signature'' sequence patterns that distinguish a specific set of protein (or nucleic acid) sequences from all other sequences. The word ''motifs'' reflects here a tacit assumption of the existence of meaningful functional and structural constraints that are unique and detectable at the sequence level. Some authors also assume the existence of a true homology (as opposite to sequence or structure similarity) relating sequences in a given set of proteins (or just domains) or nucleic acids primary structures (see also sequence pattern and motif descriptor).
2. Motif is a pattern that can be considered a letter (unit of pattern) in an alphabet that is adequate for studying a specific correlation between sequences and their functional or structural role.

Motif Descriptor
A data structure used to define a sequence motif. Best- known descriptors include consensus sequences, weight matrices, and profiles.

Sequence Pattern
Given a k-gram alphabet, we select k-grams that we call *motifs* (meaningful strings) and k-grams that we call *punctuations* (semantically empty strings). (Heuristic principles for such choice are complex because they do involve knowledge of ''extra-sequential'' facts.) A *sequence pattern* is then a string of motifs and punctuations that begins and ends with a motif. *Contiguous Pattern* is a sequence pattern that does not contain punctuations whereas *noncontiguous pattern* is a sequence pattern that does contain punctuations.

Distance Chart
We select a particular k-gram to be a motif and then consider oligonucleotides separating the instances of this k-gram to be punctuations. The frequency of occurrence of punctuations plotted against their length is a *distance chart*. We refer to a distance chart in which the motif is not allowed to be a substring of any punctuation as the *shortest distance chart*.

Code
A mapping from one symbolic representation (input representation) of a system into another representation (output representation). If the input and output representations can be expressed in the form of elementary symbols chosen from finite alphabets, a code can be seen as a relation between input and output alphabets.

In a narrow sense, pragmatic computational biology is today's equivalent of theoretical molecular biology of the 1970s and 1980s combined with genome bioinformatics of 1990s and early 2000s. Similarly, to the latter it aims toward extended interpretation of laboratory and computational experiments in molecular genetics (also known as functional genomics), molecular evolution, and structural biology. The ''extended interpretation'' consists of several activities, such as the following:

1. Relating the mechanistic and the informational aspects of biological phenomena through appropriate generalization and modeling, for example, postulating the triplet nature of the genetic code before it had been determined experimentally.
2. Devising principles for analyzing inexact data (quantitative representations of qualitative descriptions included), for example, database design, annotation, and searches; logic of heuristic reasoning.
3. Relating principles and laws inferred from studies at the molecular level with those derived from studies of organisms, populations, and ecosystems, for example, molecular evolution, molecular evolutionary genetics.

4. Deriving properties of biological systems from principles of physics and chemistry, for example, biological thermodynamics and kinetics; theories of origin of life; molecular mechanics.
5. Modeling (usually mathematical) properties of laboratory instrumentation and designing experiments, for example, analysis and interpretation of molecular spectra, X-ray data, electrophoretic data, microchips, and so on.
6. Modeling properties of computational tools and designing computational experiments, for example, sequence alignment.

   These activities often draw on methods that in themselves are established research areas with their own methodological foundations. Some of the methods pertain to physics (for instance, molecular mechanics), some to chemistry (for example, reaction kinetics) and yet others are parts of applied mathematics (combinatorics, for example) or computer science (for instance, theory of algorithms). Pragmatic computational biology differs from chemistry, physics, and even biochemistry by systematically exploring symbolic aspects (besides the material ones) of the biologic role(s) of nucleic acid and protein sequences.

   In a larger sense, pragmatic computational biology is concerned with cognitive systematization of concepts, theories, models, and observations that could contribute to an explanation of the phenomenon of life itself. In this (larger) sense, the principles of modeling biological systems appear to be more important than design and interpretations of specific experiments. A nonexhaustive list of activities pertaining to the larger aspect of pragmatic computational biology includes the following:
7. Developing a general system theory and research on specific classes of general systems, for example, anticipatory systems and their use for the description of (biochemical) reaction networks.
8. Developing foundations of logic and mathematic such that the resulting mathematical objects would be appropriate for modeling biological systems, for example, theory of categories as a language for formulating models and theories.
9. Developing foundations of general information theory and information science, for example, work on semantic and pragmatic theories of information, knowledge representation, data integration, and so on.

Activities 7 to 9 draw on methods from other research programs such as systems theory, cognitive science, logic, and epistemology but do not belong to the current paradigms of these fields.

This article is primarily devoted to those aspects of computational biology that pertain to sequence analysis and genomics (activities 1 and 2 above) and thereby are of interest to molecular biologists proper. However, in order to satisfy those readers who would like to predict future research directions in the field, a brief discussion of topics belonging to the larger aspect of computer-assisted systems biology (activities 7–9 above) is given in Sect. 6.

1 Preliminaries

1.1 Codes and (Biological) Function: A Logical Trap

The focus on the relationship between biopolymer (nucleic acids and proteins) sequences and possible mechanisms of biological processes makes "code" the central, unifying metaphor in molecular biology. From the early period in molecular biology, biopolymer sequences and structures were thought of as texts that carry encoded messages. The three best-known "biological codes" are

1. Watson-Crick-Chargaff base-pairing rules,
2. translation code for protein biosynthesis (the genetic code), and
3. cleavage sites for restriction enzymes.

In the past, many biologists assumed that more *functional codes* of this kind existed. For instance, we could think of replication code, homologous and illegitimate recombination codes, mutation hot-spots code, protein or RNA folding codes, and so on. However, the adequate description of biological function at the molecular level is a formidable task. It requires knowledge of a great deal of mechanistic details that constitute the function. This is a major methodological obstacle in specifying a functional code. In most cases in which we know or surmise that a code exists, we are unable to appropriately describe the biological function concerned (the genetic code is a notable exception from this common situation).

1.2 Classification Codes

The foregoing methodological problems can be avoided when we replace the notion of functional codes by an alternative concept of *classification codes*. In principle, there are many-to-one mappings from a set of patterns found in (or resulting from) a class of sequences into descriptors (such as a name or a list of features) of this class. We specify a classification code by just listing patterns from its domain. We call each individual pattern from the list a *classification code word* or just a *code word*. Not every pattern found in a given collection of sequences is a classification code word. To qualify as a code word, the pattern must be *significant* according to predetermined criteria.

1.3 Pragmatic Inference

The criteria of significance usually involve a complex heuristics called *pragmatic inference*. (The name indicates a focus on the "rules" of usage for patterns). Pragmatic inference explores the entire body of available biological knowledge in addition to statistical analyzes. The resulting measure of significance often does not correspond to statistical significance because the rules of pragmatic inference are different from the rules of statistical inference. However, statistical modeling is a vital part of those steps of pragmatic inference in which selection of motifs and punctuations is made. Figure 1 shows a conceptual scheme of pragmatic inference for sequence research as seen by most computational biologists.

1.4 Determining Classification Code Words

Methods of determining code words draw on several assumptions concerning those patterns of characters (from an elementary alphabet) that are correct code

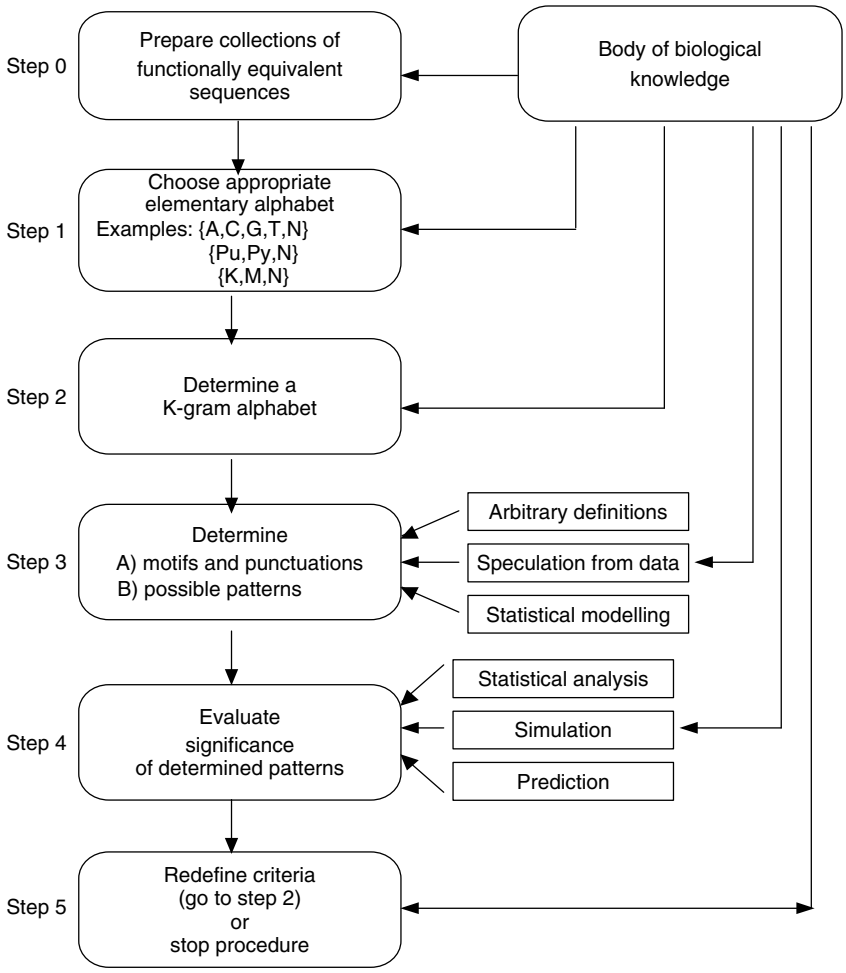

Fig. 1 General protocol of pragmatic inference pertaining to computer-assisted sequence analysis. Vaguely defined "biological knowledge" is taken into account at every step of inference.

words. A nonexhaustive list of assumptions includes:

A1. Relative frequency of a given code word should be the same (with the appropriate accuracy) in all sufficiently long sequences from a given functional class. (For sequences of infinite length, we expect that the relative frequencies converge to definite, invariant values (probabilities).)

A2. Probabilities of at least some individual code words should markedly differ from one another in all sequences from a given functional class.

A3. Probability distribution of code words should be the same (with appropriate accuracy) in all sequences from a given functional class.

A4. Selected code words should occupy distinct relative positions in every sequence from a given functional

class. (This assumption is known in linguistics as a postulate of existence of distributional structures.)

For methods to determine classification code words from corpora of sequences, explore assumptions A1 to A3. The most important are perhaps those based on coincidence indices (string length test and string repetition test) or on Markov analyses (including hidden Markov chains and nonhomogeneous Markov chains). A couple of powerful methods explore distributional structures (assumption A4) in the form of distance charts or Fourier analysis.

Knowing classification code words has practical consequences. It allows us to develop algorithms for prediction of putative functional domains in unannotated sequences. These algorithms (and the corresponding software) are of paramount importance for all genome-sequencing projects but we shall not discuss them here. The relevant discussion can be found in specialized publications on computational biology and genomics listed at the end of this article.

2 Statistical Modeling and Frequency Counts

To determine how "unusual" the occurrence of a given k-gram in a long sequence is, we have to compare the occurrence frequency in the data with the frequency expected from a model of chance.

It is in general a laborious task to find the best model of chance (i.e. prior probability distribution) for a given situation. A model often used in sequence research is a *Bernoulli text* in which all 1-grams occur independently of each other and with probabilities equal to each other. The corresponding probability distribution is known as *discrete uniform distribution* (DUD). (The reverse distribution assigns a k-gram to a given probability.)

Let determined from data frequency of ith k-gram be $F(i)$. Let the expected frequency of this k-gram be $F_0(i)$ and the variance (determined from a model of chance) be $V(i)$. The "degree of unusuality" of the occurrence of ith k-gram in the data is a function of $F(i)$, $F_0(i)$, and $V(i)$. The most common such function is a *z-score* defined as:

$$z(i) = \frac{F(i) - F_0(i)}{\sqrt{V(i)}} \qquad (1)$$

After having calculated z-score $z(i)$, we compare it with a threshold value z_0.

If $|z(i)| > z_0$, we consider the frequency of ith k-gram unusually high for $z(i) - z_0 > 0$ (overrepresentation) or unusually low for $z(i) - z_0 < 0$ (underrepresentation).

2.1 Nonoverlapping and Overlapping Frequency Counts

There are two general ways of calculating k-gram frequencies in a given long sequence (of length L): nonoverlapping count and overlapping counts. In the case of nonoverlapping count, we take into account k-grams in positions 1, $1 + k$, $1 + 2k, \ldots, 1 + mk < L$. The number $(m + 1)$ of k-grams counted in this way equals the integer part of L/k. Cases of overlapping counts of k-grams differ from each other by "counting steps" of 1 through $k - 1$ (counting step k is nonoverlapping count). In the overlapping count of step 1 we take into account k-grams in positions $1, 2, 3, \ldots, L - k + 1$ and there are exactly $L - k + 1$ k-grams in the sample of total length L. (This counting is equivalent to shifting the window of length k by

1 nucleotide at the time). If we chose a counting step of 2 and k is greater than 2, we take into account k-grams in every other position (i.e. 1, 3, 5, . . ., and so on). Counting step of 3 (if k is greater than 3) means taking into account every third position (i.e. 1, 4, 7, . . ., and so on). Most molecular biologists understand the overlapping count as a count of step 1 and we will use this convention in this article (i.e. we will not discuss cases of counting steps other than 1 and k).

When the elementary alphabet has n letters (1-grams) and when k is fixed, the k-gram alphabet contains $N = nk$ elements. In a Bernoulli text of length L the expected frequency of each k-gram is therefore $F_0 = L/nk$. For the nonoverlapping count variance is a simple function of n, k, and L given by the equation

$$V = \frac{L}{n^k} \cdot \left(1 - \frac{2k-1}{n^k}\right) \qquad (2)$$

For the overlapping, count variance is no longer a simple function of n, k, and L and has to be calculated for each individual k-gram separately. The reason for this complication is the variance's dependence on the *self-overlap capacity* of individual k-grams.

The self-overlap capacity of a given k-gram S is determined from a polynomial:

$$K_S = \sum_{i=0}^{k-1} a_i \cdot x^i \qquad (3)$$

Coefficients a_i equal 1 if the first and last $(k-i)$-grams in S are identical and equal to 0 otherwise. For example, the polynomial for trinucleotide GGG is $K_{GGG} = 1 + x + x^2$. For trinucleotides GAG and GAT, we have $K_{GAG} = 1 + x^2$ and $K_{GAT} = 1$ (no self - overlap) respectively.

The variance of frequency distribution for a k-gram S in a Bernoulli text of length L over an elementary alphabet containing n letters is a function of $K_S(1/n)$ given by the formula:

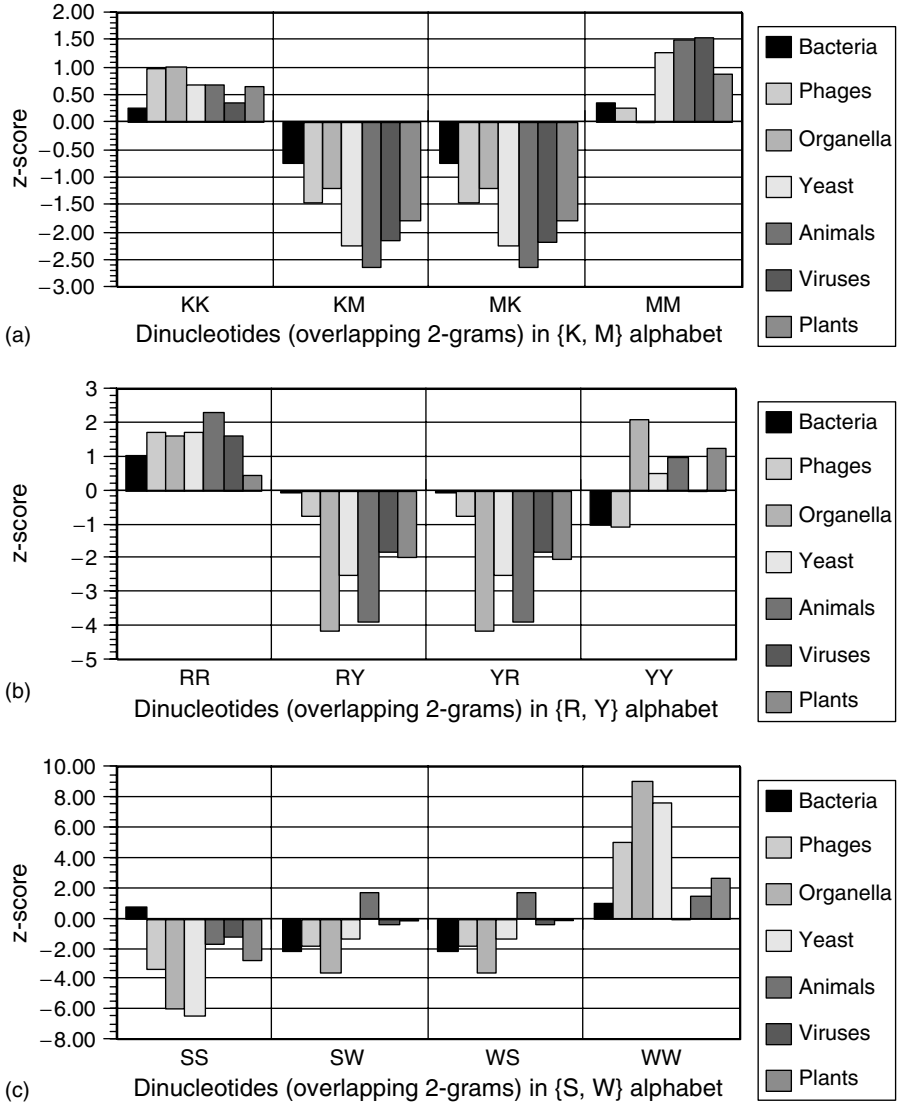
$$V_S = \frac{L}{n^k} \cdot \left[2K_S\left(\frac{1}{n}\right) - 1 - \frac{2k-1}{n^k}\right] \qquad (4)$$

Fig. 2 Examples of dinucleotide frequency counts in representative (large) samples of DNA sequences from seven different classes of genomes. Three different elementary alphabets were taken into account. (a) – {K, M} alphabet, where K is either guanine or thymine and M is either adenine or cytosine. Assuming that the threshold z-score values for unusually high frequency is +3 and for unusually low frequency is −3, none of dinucleotides over this alphabet occur significantly more often or significantly less often than others in all sequence samples studied. However, ''complex'' dinucleotides KM and MK tend to be slightly but systematically underrepresented. (b) – {R, Y} alphabet, where R stands for purine (adenine or guanine) and Y stands for pyrimidine (cytosine or thymine). ''Complex'' dinucleotides RY and YR appear to be unusually underrepresented in organella and animal (i.e. primate, rodent, other mammalian, other vertebrate and invertebrate) genomes. This underrepresentation might be due in part to the well-known avoidance of long alternating purine-pyrimidine tracks (sequences with a potential for B-DNA – Z-DNA tertiary structure transition). Note that in other genomes (bacteria, phages, yeast, viruses, and plants), slight underrepresentation of RY and YR takes place as well. (c) – {S, W} alphabet, where S stands for either guanine or cytosine and W stands for either adenine or thymine. It can be seen that dinucleotide SS is underrepresented in phage, organella (mitochondria and chloroplast) and yeast genomes. In contrast, dinucleotide WW is overrepresented in these genomes. Notably, dinucleotides SW and WS are significantly underrepresented in organella (z-score < -3) and tend to be underrepresented in other genomes as well.

Failure to consider self-overlap capacity in overlapping counts leads to huge errors (hundreds of percent) in variance calculation, particularly in cases of small-size elementary alphabets and large values of k. (Variance for nonoverlapping count (Eq. 2) can be derived from Eq. 4 by putting $K_S(1/n) = 1$ (no self-overlap).)

2.2 Ad Hoc (Simple) Frequency Counts

Examples of the overlapping 2-gram frequency counts in seven large collections of DNA sequences are shown in Fig. 2. Although the "folklore" of describing and interpreting k-gram frequency counts



resembles descriptive biology of the nineteenth century (see caption to Fig. 2), it plays an invaluable role in selecting elementary alphabets and k-gram candidates for motifs.

2.3 Ranked Oligonucleotide Frequencies; Yule Distribution

Ranks of word frequency in printed alphabetic languages appear to follow the so-called *Zipf distribution*, which is given by the equation:

$$F = a \cdot R^k \quad \text{and } k < 0 \qquad (5)$$

where F is frequency of occurrence and R is rank from most frequent to least frequent.

The same distribution also characterizes a host of nonlinguistic phenomena such as the number of species per genus, the number of papers per author in a given field of science, the distribution of income, and the population of cities in a nation.

Attempts to find a fit of ranked oligonucleotide frequencies to Zipf distribution failed soon after the first nucleotide sequences were known. It is clear by now that short oligonucleotide frequencies from all known genomes do not follow Zipf distribution but a more general 3-parameter density called the *Yule distribution*, which is given by the equation:

$$F = a \cdot R^k \cdot b^R \qquad (6)$$

Tab. 1 Fit of Yule equation to ranked hexanucleotide frequencies in several large collections of intron and exon sequences. When plotted on log–log coordinates, all of the data exhibit the convex form shown in Fig. 3. The mean values of parameters a, b and k in introns and exons are the same within error limits (a-intron $= 0.0034 \pm 0.0026$; a-exon $= 0.0018 \pm 0.0005$; b-intron $= 0.9981 \pm 0.0036$; b-exon $= 0.9994 \pm 0.0001$; k-intron $= 0.25 \pm 0.11$; k-exon $= 0.15 \pm 0.03$). This implies that Yule parameters should not be used to discriminate between coding and noncoding regions in nucleotide sequences (the sampling errors in noncoding regions are too high). However, high ρ^2 values show that fit to the Yule distribution is excellent for both coding and noncoding regions regardless of the species. (Based on Martindale, C., Konopka, A.K. (1996), *Comput. Chem.* **20**(1), 35–38.)

	Base pairs	***Yule distribution***			
		a	***k***	***b***	ρ^2
Primates introns	346,953	0.0016	−0.15	0.9994	0.96
Primates exons	500,899	0.0017	−0.14	0.9993	0.97
Vertebrates introns	232,272	0.0017	−0.16	0.9995	0.96
Vertebrates exons	370,327	0.0021	−0.18	0.9994	0.97
Invertebrates introns	181,184	0.0034	−0.28	0.9995	0.99
Invertebrates exons	499,601	0.0016	−0.15	0.9994	0.95
Organella introns	105,189	0.0045	−0.33	0.9996	0.99
Organella exons	531,943	0.0020	−0.17	0.9994	0.97
Plant introns	255,535	0.0027	−0.24	0.9995	0.98
Plant exons	588,172	0.0015	−0.13	0.9994	0.95
Yeast introns	18,821	0.0089	−0.43	0.9999	0.97
Yeast exons	333,789	0.0025	−0.19	0.9993	0.99
Viral introns	75,359	0.0015	−0.15	0.9995	0.99
Viral exons	733,231	0.0011	−0.09	0.9995	0.89
Bacterial genes	876,257	0.0015	−0.12	0.9993	0.95
Phage genes	353,104	0.0022	−0.19	0.9994	0.98

where F is frequency and R is the rank; a, b, and k are parameters.

Zipf distribution (Eq. 5) is a special case of the Yule distribution (Eq. 6) in which parameter $b = 1$. Even if b is very close to 1 but not exactly equal to 1 (for instance $b = 0.9995$), the Yule distribution remarkably differs from the Zipf distribution.

Parameters of Yule distribution for hexanucleotide frequencies in large collections of intron and exon sequences are shown in Table 1. It appears that both intron and exon data fit the Yule distribution extremely well (and about equally well; see caption to Table 1). Example plots (in log-rank-log-frequency coordinates) of the Yule distribution are shown in Fig. 3.

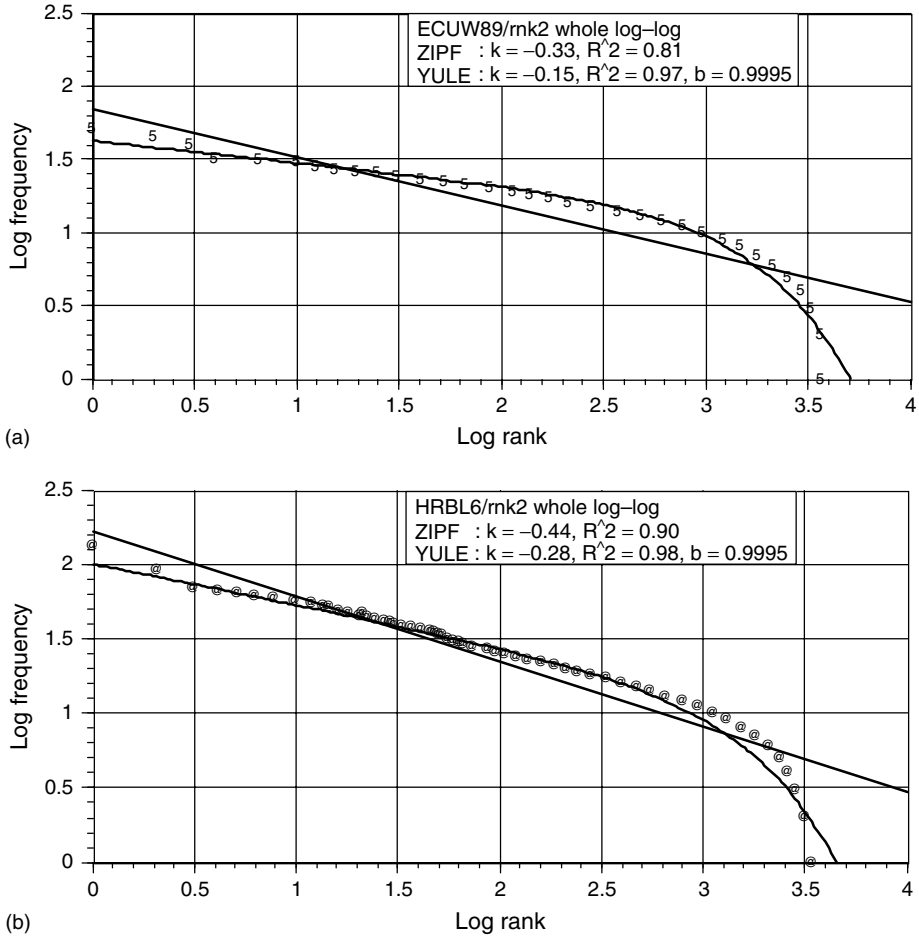


Fig. 3 Ranked hexanucleotide frequencies fit the Yule distribution (convex lines on Figures (a) and (b)) much better than the Zipf distribution (straight lines on Figures (a) and (b))
(a) ECOUW89 is a long sequence (176,195 nt) in which 82.1% of nucleotides constitute protein-coding regions. (b) HUMRETBLAS is a long sequence (180,388 nt) in which only 1.5% of nucleotides belong to exons [Based on: Martindale, C. Konopka, A.K., (1996) *Comput. Chem.*, **20**(1), 35–38].

3
Measuring Deviations from Discrete Uniform Distribution (DUD)

3.1
Entropy and Redundancy of Nucleotide Sequences

The mathematical apparatus of Shannon's Theory of Communication (''Information'' Theory) has been applied to biology quite against Shannon's preferences. In 1954, he dismissed psychology and biology as fields of science that could benefit from applying his theory because he believed that semantic aspects of communication are more important in these fields than syntactic aspects. Of course, he was unaware of the important role that statistical studies of nucleotide and protein sequences would play in biology. Today, we know that indeed communication theory does not explain much of biology (nor did anyone sane ever expect it to do so) but, on the other hand, it is an extraordinary source of statistical methods for studying sequences.

Shannon's studies of k-grams of letters in printed alphabetic languages have been a spectacular application of his theory of communication (''information'' theory). The central concept in these studies is an abstract device (called *source*) that generates sequences of symbols (messages) chosen from a finite alphabet by means of a random mechanism. Particularly important are ergodic sources in which the random mechanism leads to ''typical'' messages with high probability (close to 1) and to ''atypical'' sequences of symbols with negligible probability. (We can say, in other words, that sequences produced by an ergodic source are statistically homogeneous.)

It has long been known that frequency distributions of letters are roughly the same in all texts written in the same language. It has then been assumed (but not proved) that any alphabetic writing system can be modeled by an ergodic source. (In particular, it has been suggested that a writing system can be regarded as a limit of a succession of ergodic Markov sources that in turn is itself an ergodic source.)

The probability distribution of letters from an alphabet of size n in a given ensemble of texts can be characterized by a function called *entropy* (of the distribution):

$$H_1 = -\sum_{i=1}^{n} p(i) \cdot \log_r p(i) \qquad (7)$$

where $p(i)$ are probabilities of letters and the log is taken to the base $r = 2$ (unless otherwise specified) and a convention $0 * \log_r(0) = 0$ is applied.

If textual elements (letters) from a finite alphabet of size n were combined in a text by chance alone, it would have to be a Bernoulli text. Therefore, the letters should occur independently of each other and with probabilities following a DUD (i.e. equal to $1/n$). The entropy of DUD obviously equals $log_r(n)$, that is:

$$H_0 = -n \cdot \frac{1}{n} \cdot \log_r \frac{1}{n} = \log_r n \qquad (8)$$

The *entropy of strings of length k* composed of characters from an (elementary) alphabet of size n is defined as

$$H^{(k)} = -\sum_{i_1=1}^{n} \sum_{i_2=1}^{n} \cdots \sum_{i_k=1}^{n} p(i_1, i_2, \ldots, i_k) \cdot \log_r p(i_1, i_2, \ldots, i_k) \qquad (9)$$

The *k-gram entropy* is defined as

$$H_k = H^{(k)} - H^{(k-1)} \quad \text{for} \quad k > 1 \qquad (10)$$

with $H^{(1)} = H_1$ given by (7) and H_0 given by (8).

Note that entropy has a dimension that is determined by the basis r of logarithmic function and by the alphabet taken into account. In the general case, when the basis of log function is r, the k-gram entropy H_k is given in r-ary units per letter and the strings of length k entropy is given in r-ary units per k-gram. The most frequently used value of r is 2. In this case, $H^{(k)}$ is in bits per k-gram and H_k in bits per letter (''bit'' is a name of 2-ary unit).

A *source* S has entropy $H(S)$ if

$$\lim_{k\to\infty} \frac{H^{(k)}}{k} \tag{11}$$

exists and equals $H(S)$.

The ergodic sources always have entropy. A given writing system (sometimes referred to as *a language*) L is assumed to be an ergodic source (a limit of a succession of ergodic Markov sources). Hence, the writing system's entropy $H(L)$ exists and is bounded by the following (obvious) chain of inequalities:

$$H(L) < \cdots < H_k < \cdots < H_3 < H_2 < H_1 < H_0 \tag{12}$$

The ratio of entropy of source to the maximum value it could have while still restricted to the same symbols is called *relative entropy* (of source). Since it follows from (12) that H_0 is the maximum value of entropy, we have:

$$H(L)' = \frac{H(L)}{H_0} \tag{13}$$

In a similar way, we can define *relative k-gram entropy*:

$$H_k' = \frac{H_k}{H_0} \tag{14}$$

Values of relative entropy are dimensionless real numbers form the interval [0, 1].

Writing system's (language) *redundancy* is defined as:

$$R(L) = 1 - H(L)' \tag{15}$$

Similarly, we can define k-gram redundancy as:

$$R_k = 1 - H_k' \tag{16}$$

It follows from (12) that $R(L)$ is higher than any k-gram redundancy, that is:

$$0 < R_1 < R_2 < \cdots < R_k < \cdots < R(L) \tag{17}$$

Because of high sampling errors of k-gram entropies in finite-length sequences, it is not obvious that the ensembles of functionally equivalent nucleotide sequences have entropy. Dedicated computational studies will be needed in the future to determine how well k-gram entropies converge to the source entropy values. For the time being, we assume that functionally equivalent sequences do have entropy and that ''functionality'' can be thought of as an ergodic source.

Table 2 shows the results of redundancy calculation for several large collections of functionally equivalent nucleotide sequences. As expected the sequences of eukaryotic illegitimate recombination regions display very high redundancy (around 20%). This is due to the frequent occurrence of mononucleotide repeats. Interestingly, the lowest redundancy can be seen for protein-coding genes and the highest for intergenic spacers and flanking regions of genes. However, because of very high error values, redundancy in exons and the corresponding introns appears to be the same even at the level

Tab. 2 Estimated redundancy in various large collections of functionally equivalent nucleotide sequences. The estimates for $k \rightarrow oo$ were obtained from regression analysis of 1- through 4-grams' or 1- through 5-grams' redundancies (depending on the length of sequences in a given collection).The error values listed are standard errors of estimate for hyperbolic regression. (Based on: Konopka, A.K. (1994) Sequences and Codes: Fundamentals of Biomolecular Cryptology, in: Smith, D. (Ed.) *Biocomputing: Informatics and Genome Projects,* Academic Press, San Diego, CA, pp. 119–174.)

	Redundancy
Human exons (in mature mRNAs)	0.070 ± 0.009
Human introns	0.082 ± 0.017
Human 3′UTRs	0.081 ± 0.020
Human 5′UTRs	0.083 ± 0.022
Human 3′ flanks of protein-coding genes	0.160 ± 0.034
Human 5′ flanks of protein-coding genes	0.122 ± 0.025
Eukaryotic exons (in mature mRNAs)	0.076 ± 0.021
Eukaryotic introns	0.087 ± 0.022
Eukaryotic Intergenic Spacers (non-RNA, nonhistone)	0.112 ± 0.007
Eukaryotic Intergenic Spacers (histone)	0.142 ± 0.027
Eukaryotic Illegitimate Recombination Regions	0.202 ± 0.032
Bacterial protein-coding genes	0.075 ± 0.023
Bacterial spacers (RNA genes)	0.090 ± 0.023
18s-rRNA genes	0.095 ± 0.040
Small nuclear RNAs	0.127 ± 0.032
16s-rRNA genes	0.118 ± 0.038
5s-rRNAs	0.092 ± 0.028
tRNAs	0.155 ± 0.041
23s-RNAs	0.127 ± 0.041
28s-RNAs	0.169 ± 0.024

of confidence of 33%. This precludes using the "function-associated" redundancy as a criterion for determining exon and intron location in unannotated sequences. This also means that redundancy is unlikely to be a basis for a classification code.

3.2 Coincidence Indices and Their Use in Sequence Analysis

pt For a discrete probability distribution $[p(1), p(2), \ldots, p(n)]$ over an ensemble of n events the *index of coincidence* can be defined as:

$$I = n \cdot \sum_{i=1}^{n} p^2(i) \tag{18}$$

For the text of finite length L, index of coincidence can be estimated as:

$$I = \frac{n \cdot \sum_{i=1}^{n} f(i) \cdot [f(i) - 1]}{M \cdot (M - 1)} \tag{19}$$

where $f(i)$ is a frequency of ith element of the alphabet n is a size of the alphabet and M is the number of elements of the alphabet present in the text (for single letters $M = L$, for strings of 2

letters $M = L - 1$ for strings of k letters $M = L - k + 1$).

The variance of I has been found to be

$$\mathrm{Var}(I) = \frac{2I \cdot (n - I)}{M \cdot (M - 1)} \qquad (20)$$

In statistical linguistics and cryptanalysis tests based on coincidence, indices are reliable tools to determine substitution block encodings. They work particularly well in the cases in which each string of the code alphabet has the same length as other strings. It also helps if the size of (encoded) ''space bars'' is negligible compared to the size of (also encoded) ''message units''.

Classification codes for different ensembles of functionally equivalent sequences can be determined by the two tests based on coincidence indices

Both, *string repetition test* and *length test*, apply to the following situation: Given a sequence of length L represented in an elementary alphabet E = {A, C, G, T}, consider m code alphabets containing $N(k) = 4^k$ strings each ($k = 1, 2, \ldots, m$ and $m \ll L$). Choose ''the best'' code alphabet (to represent a given sequence) from the m alphabets given.

In the string repetition test we pick the k-th alphabet and calculate coincidence index (19) along with its variance (20) in our sequence of length L (i.e. containing $M = L - k + 1$ ''overlapping'' or $M' = \mathrm{Int}\{L/k\}$ ''nonoverlapping'' strings belonging to the alphabet of $N(k)$ elements). For a Bernoulli text, the k-gram probability distribution is a DUD and therefore $I_{\mathrm{expected}} = 1$. The z-score of I in a given alphabet is:

$$z(I) = \frac{I - 1}{\sqrt{\mathrm{Var}(I)}} \qquad (21)$$

After calculating $z(I)$ for each alphabet, we consider those alphabets that maximize (21) to be ''the best''.

In the string length test, mean coincidence indices (per letter) in k-grams over an n-letter alphabet are compared with the coincidence index over 1-grams in *entire* sequence. We pick the kth alphabet and calculate the coincidence index for all letters at all positions $j = 1, 2, \ldots, k$ within each k-gram in a given sequence, that is:

$$I(j) = \frac{n}{M \cdot (M - 1)} \cdot \sum_{i=1}^{n} f(i,j) \cdot [f(i,j) - 1] \qquad (22)$$

where $f(i,j)$ is the frequency of ith letter (out of n) at the jth position of a k-gram. Of course, for nucleotide sequences expressed in {A,C,G,T/U) alphabet we have $n = 4$, while for binary alphabets such as {R,Y} or {K,M}, n equals 2.

The above calculations provide us with a vector $\boldsymbol{J} = [I(1), I(2), \ldots, I(k)]$ from which we can determine the mean coincidence index $\langle I \rangle$, that is:

$$\langle I \rangle = \frac{1}{k} \cdot \sum_{j=1}^{k} I(j) \qquad (23)$$

The expected value of $\langle I \rangle$ for nucleotide sequences in {A, C, G, T} alphabet can be estimated from (19) with $M = L$ (number of 1-letter subsequences equals the length of sequence) and $n = 4$, that is,:

$$\mathrm{E}(\langle I \rangle) = \frac{4 \cdot \sum_{i=1}^{4} f(i) \cdot [f(i) - 1]}{L \cdot (L - 1)} \qquad (24)$$

The corresponding variance is obtained from (20) by again putting $M = L$ and $n = 4$ (if we use {A, C, G, T/U} alphabet; for binary alphabets such as {R, Y} we would need to put $n = 2$ and $M = L$), that is:

$$\mathrm{Var}(\langle I \rangle) = \frac{2I \cdot (4 - I)}{L \cdot (L - 1)} \qquad (25)$$

The z-score for this test is then:

$$z(\langle I\rangle) = \frac{\langle I\rangle - \mathrm{E}(\langle I\rangle)}{\sqrt{\mathrm{Var}(\langle I\rangle)}} \qquad (26)$$

After calculating $z(\langle I\rangle)$ for each alphabet, we consider the alphabet that maximizes (26) to be ''the best.''

Both tests indicate unambiguously (see Table 3) that the trinucleotide code is the best to represent protein-coding regions in nucleotide sequences. This result is remarkable because it leads to a rediscovery of codons of the genetic code solely on the basis of the statistical structure of sequences. This means that knowledge of the protein-coding function of genes is not required to find genes among other sequences. Needless to say, methodology of this kind can be used for practical purposes of finding exons in unannotated sequences.

In fact, about 98.5% of known translated regions of genes (exons and bacterial genes) display excessively high, positive values of $z(\langle I\rangle)$ for the alphabets of 3-grams, 6-grams, 9-grams, and generally, $3m$-grams ($m = 1, 2, 3, \ldots, 20$). In addition, the large fractions of remaining 1.5% are the exons that are subject to alternative splicing (i.e. are also parts of introns).

As far as sequences that are not translated are concerned, the results of string length test are less clear. For example, in a large sample of nuclear eukaryotic introns, about 20% of the sequences test positively for the code word's length 2 [i.e. $2m$-grams ($m = 1, 2, 3, \ldots$) are unambiguously indicated by the test (26); see Table 3]. Another 3% of intron sequences display clear preference for strings of length 4. Both these results are consistent with the 2-base periodicities in large collections of intron sequences (see Sect. 5). However, the test (26) also indicates that about 7% of intron sequences display a clear preference for strings of length 5 and there exist introns (only about 1.3% in the sample collection) that ''favor'' heptanucleotides.

There are at least three plausible interpretations of the above findings. One possibility is that there are many different kinds of introns playing different biological roles before being spliced out of hnRNAs. Another possibility is that the ''intronic'' code alphabet contains strings of variable length. In such a case, the string length test would detect the mean length of a code word but not the actual lengths of individual code words. Finally, it may well be that only fragments of introns are involved in some (unknown) biological processes. In such a case, long stretches of sequence within introns would not code for any function and therefore there would be no reason to ''employ'' a statistically distinguishable k-grams' alphabet. This last situation would be similar to a text in which long strings of space bars separate individual words (or even letters) and many different symbols would be allowed to stand for a space bar.

As far as viral introns are concerned they display conspicuously high z-scores for string lengths multiples of 3 (examples are listed in Table 3), as do many mitochondrial introns (data not shown). This ''exonic'' characteristics is quite unexpected in introns but can be easily explained by the fact that viral genomes contain overlapping genes. A given viral intron can be an intron in one gene and a part of exon in another (overlapping) gene. Therefore, the ''exonic'' characteristics (in the form of preference for strings of lengths multiple of 3) of viral introns can be detected. Similarly, those mitochondrial introns that display ''exonic'' characteristics (code word lengths 3, 6, 9, . . .) overlap

Tab. 3 Examples of *z*-scores calculated from the string length test [formula (26) in the text] for sequences belonging to different functional classes. Only string lengths between 2 and 9 are listed. (Calculations based on: Shulman, M.J., Steinberg, C.M., Westmoreland, N. (1981) The coding function of nucleotide sequences can be discerned by statistical analysis, *J. Theor. Biol.* **88**, 409–420.)

with genes that encode the endonuclease responsible for their splicing.

4 Noncontiguous Patterns and Distance Charts

Distributional structures in nucleotide sequences from the same functional class (as introns, exons, tRNAs, 5sRNA, illegitimate recombination sites, and so on) can be seen on k-gram distance charts. If there were no distributional structures in sequences studied, there would be no particular reason for any punctuation length to occur more frequently than other lengths. In other words, with no distributional structures, punctuation lengths should follow a discrete, uniform frequency distribution. When the distributional structures are present, some punctuation lengths should be much more frequent and some others much more rare than expected from discrete, uniform distribution.

Similar reasoning applies to the shortest distance charts. In the absence of distributional structures, the frequency of punctuation lengths in the shortest distance charts would follow geometric distribution. Again, when distributional structures are present, some punctuation lengths will occur more frequently and some others less frequently than expected from geometric distribution.

Distance charts (z-scores with regard to discrete, uniform distribution) for motif AC in large collections of nuclear introns and exons from animal genomes (primates, rodents, other mammals, vertebrates, and invertebrates) are shown in Fig. 4(a). The charts for an internally mirror-symmetric motif ACA appears in Fig. 4(b). The corresponding shortest distance charts (z-scores with regard to the appropriate geometric distribution) are shown in Figs. 4(c and d). It is clearly seen from Figs. 4(a–d) that exon and intron sequences display k-gram distributional structures and that these structures are transparently different for exons than for introns. The former display a strong overrepresentation of punctuation lengths 0, 3, 6, ... and generally $3k$ ($k = 0, 1, 2, 3, \ldots$) for trinucleotide ACA whereas the later favor distances $0, 2, 4, \ldots$ and generally $2k$ ($k = 0, 1, 2, \ldots$) for dinucleotide AC. Inspection of shortest distances (Figs. 4(c and d) shows that preferred nearest distances between ACs are 0 and 2 in introns. However, exon preferred shortest distances between ACAs (Fig. 4d) are the same as distances from Fig. 4(b) (i.e. 0, 3, 6, 9, ... and generally $3k$). These findings suggest that AC is involved in ''true'' 2-base periodic patterns in introns whereas ACA is involved in strongly pronounced 3-base quasi-periodic patterns in exons.

Other than AC, nonhomopolymeric dinucleotides and the vast majority of nonhomopolymeric (including mirror-symmetric) trinucleotides display distance charts almost identical to those shown in Fig. 4 (data not shown). This suggests that predominant patterns in exons and introns are 3-base quasi-periodic arrangements of trinucleotides and 2-base periodic repeats of dinucleotides respectively.

Notably, distance charts from the above example allowed us to rediscover the triplet structure of the genetic code from exon sequences alone (i.e. without taking into account our knowledge of the genetic code). In the light of this rediscovery, 2-base periodicities observed in introns must reflect meaningful, intron-specific distributional structures.

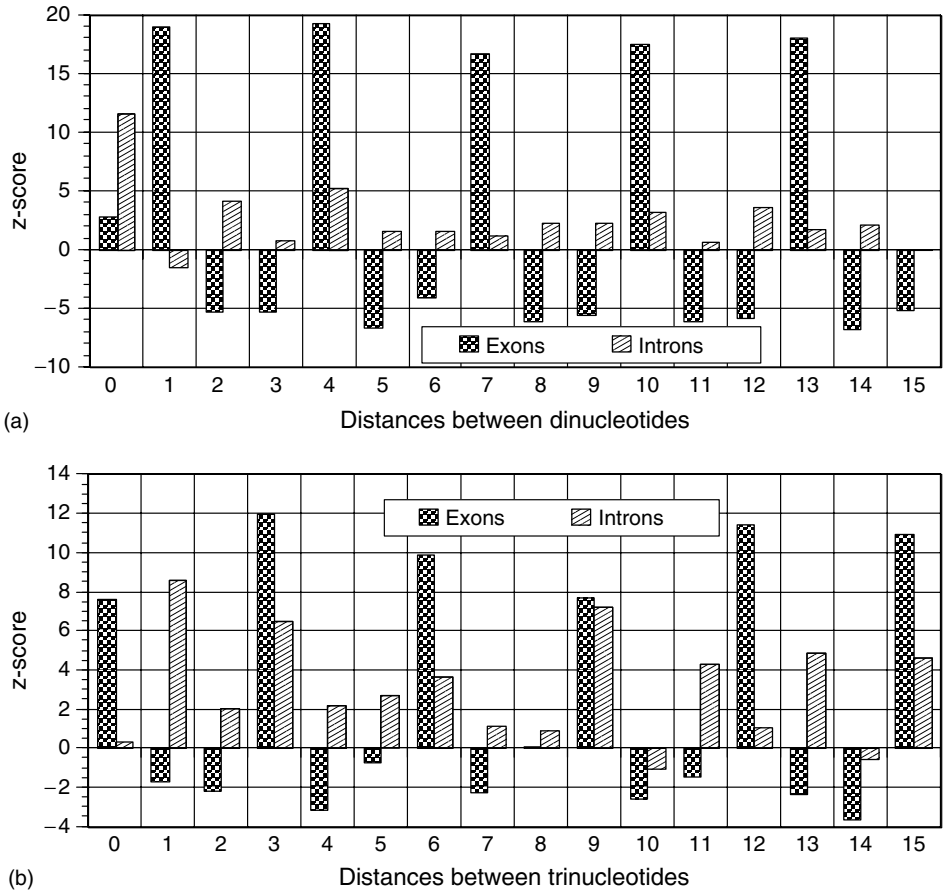

Fig. 4 Examples of distance charts for nonhomopolymeric dinucleotides and the corresponding mirror-symmetric trinucleotides in large corpora of animal, nuclear exons and introns. (Based on and modified from: Konopka, A.K., Smythers, G.W. (1987b) *Comput. Appl. Biosci.* **3,** 193–201.) (a) – Dinucleotides tend to be separated by gaps of lengths divisible by 2 in introns. In exons, we can see a tendency of those gaps lengths to follow an arithmetic progression with increment 3. This leads to predominant distances of 1, 4, 7, 10, . . . and generally $1 + 3k$ ($k = 0, 1, 2, \ldots$). (b) – Trinucleotides (including the mirror-symmetric ones) tend to be separated by gaps of lengths divisible by 3 in exons. (c) – Shortest distance chart displays the same predominant dinucleotide distances in exons as the distance chart (Fig. 2a). However, the predominant shortest distance for dinucleotides in introns is 0 nucleotides. This means that 2-base periodicity implied by distance chart is a ''true'' periodicity (see the text and Fig. 1). (d) – Shortest distance chart for trinucleotides in exons displays the same, divisible by 3, predominant distances as the distance chart from Fig. 2b. The 3-base periodicity implied by Fig. 2b is not a ''true'' periodicity but a 3-base quasi periodicity (see the text and Fig. 1).

Fig. 4 (*Continued*)

5 Local Compositional Complexity: A Maximum Entropy Principle

5.1 Local Compositional Complexity

Local compositional complexity can be defined by two different measures. Both of these measures are based on a concept of *repetition vector* (sometimes called *complexity state vector*). For a string of length N, the repetition vector is:

$$\tilde{\boldsymbol{n}} = (n_1, n_2, \ldots, n_L) \qquad (27)$$

where L is the number of letters in the alphabet, and n_i is the number of occurrences of letter i in the string (i.e. $n_1 + n_2 + \cdots + n_L = N$). The elements of the repetition vector are ordered according to size, so $n_1 \geq n_2 \geq n_3 \ldots \geq n_L$. For example, the string ACTGAAGT has the repetition vector (3,2,2,1). The repetition

vector is not dependent on the order of the letters, so any permutation of a given string will have the same repetition vector, for example, AAATTGGC also has the repetition vector (3,2,2,1). Similarly, any permutation of the alphabet yields a string with the same repetition vector, for example, TGACTTCA has the repetition vector (3,2,2,1).

One measure of compositional complexity is:

$$\mathcal{K}_1 = (1/N) * \log_r \left(N! \Big/ \prod_{i=1}^{L} n_i! \right) \quad (28)$$

where L, N, and n_i are defined as above and r equals to L. For example, for a DNA fragment, one alphabet would be the possible nucleotide bases in the DNA, that is, adenine, cytosine, guanine, and thymine, or A, C, G, T. In this case, L and r would be 4, and the nis would be the numbers of As, Cs, Gs, and Ts in the fragment.

Another measure of complexity is based on Shannon entropy:

$$\mathcal{K}_2 = -\sum_{i=1}^{L} [((n_i/N) * \log_r(n_i/N))] \quad (29)$$

where n_i, N, L, and r are the same as above.

Although $\mathcal{K}_1$ and $\mathcal{K}_2$ converge as N approaches infinity, for short oligonucleotides they differ significantly.

5.2 Surprisal

We can define a *complexity class* as a set of strings that have the same repetition vector, and therefore the same complexity. For a string of length $S \gg N$ we can calculate the *surprisal*, or *log-odds ratio*, for each such class.

Surprisal (log-odds ratio) is defined as:

$$\mathcal{S}(\tilde{\boldsymbol{n}}) = \log_r [P_{\text{observed}}(\tilde{\boldsymbol{n}}) / P_{\text{expected}}(\tilde{\boldsymbol{n}})] \quad (30)$$

where $\tilde{\boldsymbol{n}}$ is the repetition vector $(n_1, n_2, \ldots, n_L)$, P_{observed} is the observed probability of the repetition vector n in the string, and P_{expected} is the *a priori* probability of the repetition vector $\tilde{\boldsymbol{n}}$ in the string. The expected probability for a given repetition vector is the sum of probabilities of each of the distinct strings that share that repetition vector. Assuming that each of the letters is equally probable, then each of these strings has equal probability, and the probability for any repetition vector class is simply the number of different strings that share that repetition vector divided by the number of possible strings. For example, for a DNA fragment and the alphabet ACGT, the total number of possible strings is L^N, the number of permutations of a given string is

$$\mathrm{w}(\tilde{\boldsymbol{n}}) = N! \Big/ \prod_{i=1}^{L} n_i! \quad (31)$$

and the number of distinct permutations of the alphabet for a given repetition vector is

$$\mathrm{F}(\tilde{\boldsymbol{n}}) = L! \Big/ \prod_{i=1}^{j} h_i! \quad (32)$$

where j is the number of distinct values among the elements of the repetition vector n, and h_i is the number of elements in $\tilde{\boldsymbol{n}}$ that have the jth value. For example, for $\tilde{\boldsymbol{n}} = (3, 2, 2, 1), j = 3, h_1 = 1$ because there is one element with the value 3, $h_2 = 2$ because there are two elements with the value 2, and $h_3 = 1$ because there is one element with the value 1. Note that $L!$ is the number of permutations of the alphabet, and it is divided to eliminate redundancy.

Thus, the *a priori* probability for $\tilde{\boldsymbol{n}}$ is:

$$P_{\text{expected}}(\tilde{\boldsymbol{n}}) = [\mathrm{F}(\tilde{\boldsymbol{n}}) * \mathrm{w}(\tilde{\boldsymbol{n}})]/L^N \qquad (33)$$

The probability distribution generated from the assumption of equal probabilities for each of the letters in the alphabet we call P_0.

5.3 Log-odds Complexity Distribution

All collections of functionally equivalent nucleotide sequences studied thus far display a linear tendency in surprisal versus complexity distributions (see two examples in Fig. 5). The slope of this linear relation is negative in all cases studied. This is interpreted as a *maximum entropy relationship* constrained by mean complexity.

It is likely that this maximum entropy relation is a general law governing all natural nucleotide sequences. (Preliminary evidence exists that protein sequences "obey" this principle as well.) On the other hand, sequences belonging to different putative functional domains display systematically different slope values. Discriminative power of the slopes is much stronger than the criteria based on sequence periodicity or uneven distribution of mononucleotides between three positions in codons. This suggests that slope values can be used as reliable classification code words.

5.4 Patchy Complexity

Strings of symbols used to determine repetition vector $\tilde{\boldsymbol{n}}$ can be generated by selecting noncontiguous nucleotides from a given (long) sequence. We shall discuss complexity of strings of L symbols obtained by taking every kth nucleotide, $k = 1, 2, \ldots, 20$, from original nucleotide sequences. *Patchy oligonucleotides* defined in this way are characterized by patchiness, k and block length, L. For instance, "normal" (i.e. nonpatchy) hexanucleotides are characterized by $k = 0$ and $L = 6$ whereas hexanucleotides obtained by concatenating (six times) every other nucleotide in a given sequence are described by $k = 1$ and $L = 6$. Similarly, octanucleotides generated by taking 8 times every third nucleotide from the original sequence are characterized by $k = 2$ and $L = 8$ but "normal" octanucleotide are of patchiness $k = 0$.

We refer to complexity calculated over repetition vectors of patchy oligonucleotides as to *patchy complexity*. Of course, the "normal" (i.e. nonpatchy) local compositional complexity is a special case of patchy complexity.

All standard results obtained for local compositional complexity of nucleotide sequences hold for patchy complexities. In particular:

1. For every value of patchiness k, the linear relation between complexity of patchy L-nucleotides and surprisal is observed. The slope values are negative in majority of cases studied.
2. The larger block length L is the more negative the slope of surprisal versus complexity relationship is (for a given k).

Examples of the relationship between slope values and patchiness for the block lengths $3 \leq L \leq 13$ in {A, C, G, T/U} alphabet are shown in Figs. 6(a–d). It can be seen in Fig. 6(a) that the relationship is clearly a modulo-3 periodic function of k for exons (minimum slope values for $k = 2$, 5 and 8; a clear period of 3) but this is not the case for introns (clear minimum at $k = 1$ for $L > 4$ as well as weakly pronounced minima at $k = 1$, 3, 5,

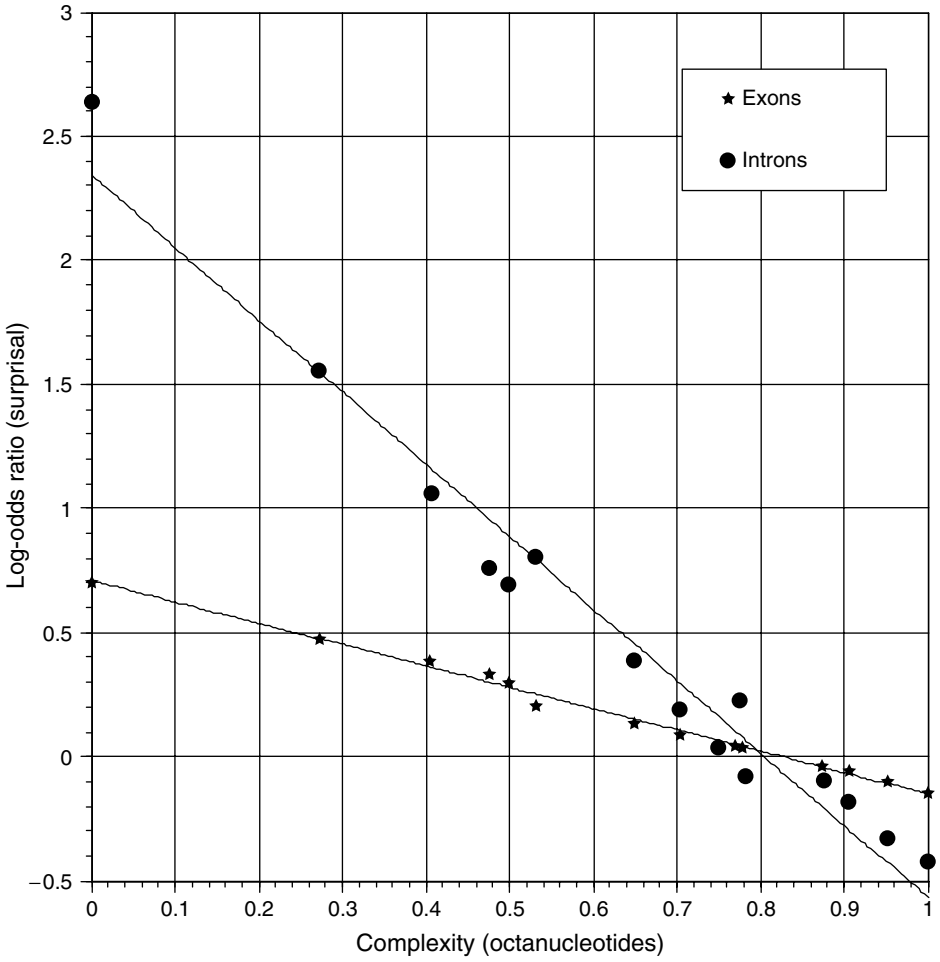

Fig. 5 Example of maximum entropy relationship between complexity and surprisal (see the text) for octanucleotides in invertebrate introns and exons. All naturally occurring nucleotide sequences studied thus far (over 30 large corpora of sequences) display a linear trend (with negative slope) for tetra- through octanucleotides. (Based on Salamon, P., Konopka, A.K. (1992) *Comput. Chem.* **16,** 117–124.)

and 7, which correspond to the well-known weak period of 2; Fig. 6b). Slopes for 3′UTR (Fig. 6c) are an increasing function of k with a very weakly pronounced minima at $k = 5$ and $k = 7$ for large L. The 5′UTRs (Fig. 6d) display a weakly pronounced period of 3 but generally lower slope values than exons. The difference between slope values for different block lengths L appears to be much more dramatic than in the case of exons.

6 Computer-assisted Systems Biology

With the passage of time, most of today's molecular biology seems to have

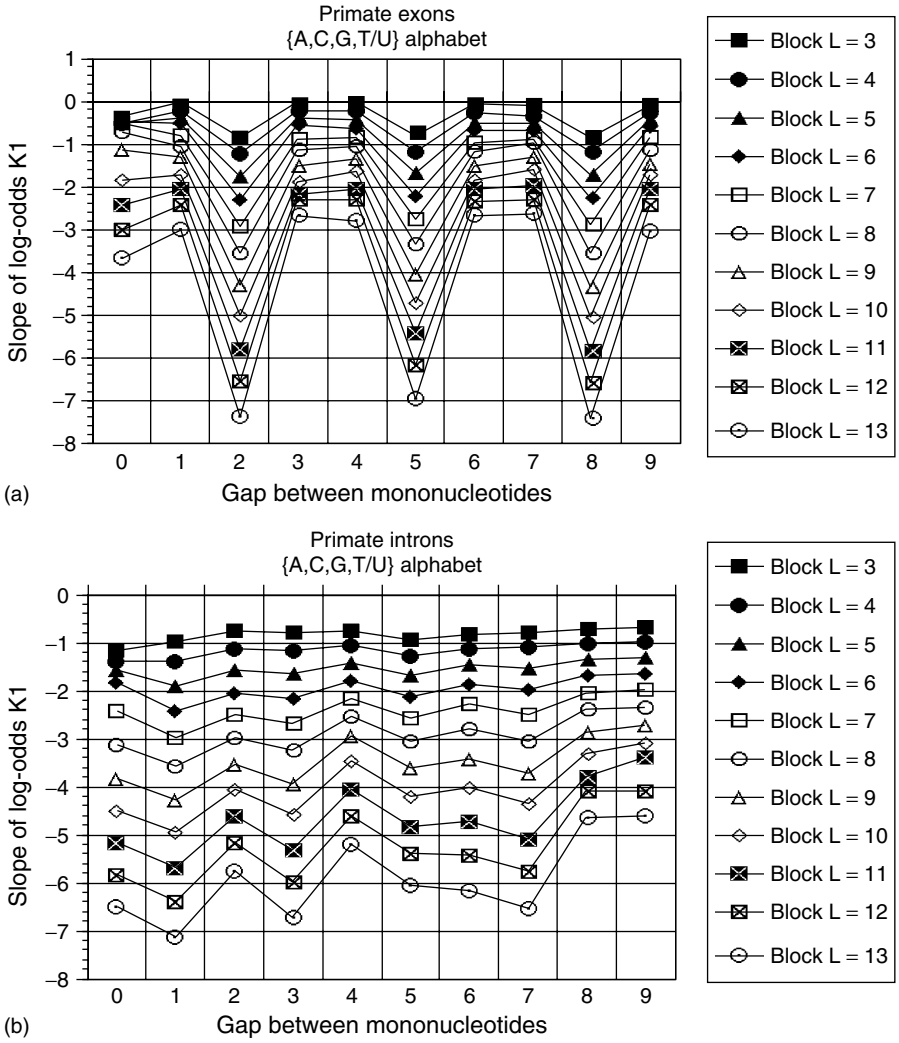

Fig. 6 Slopes of log-odds patchy complexity distributions in (a) – Primate exons (b) – Primate introns (c) – Human 3′ untranslated regions of protein-coding genes (3′-UTRs) (d) – Human 5′ untranslated regions of protein-coding genes (5′-UTRs) (Based on unpublished work by Konopka, A.K., Felts, B.E., and Hand, C.; Extended Abstracts – Open Problems of Computational Molecular Biology (4), Telluride, CO, (1994) and Notes – Gene-Finding and Gene Structure Prediction workshop, Philadelphia, PA (1995).)

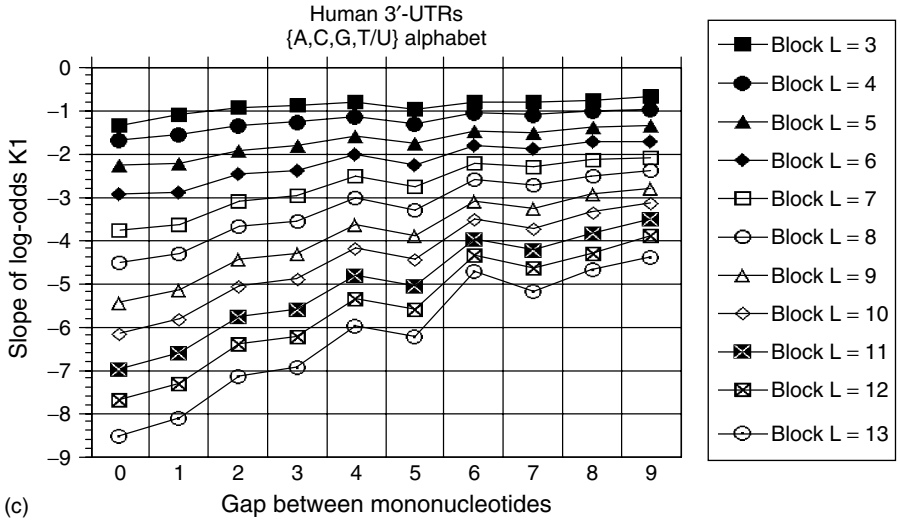
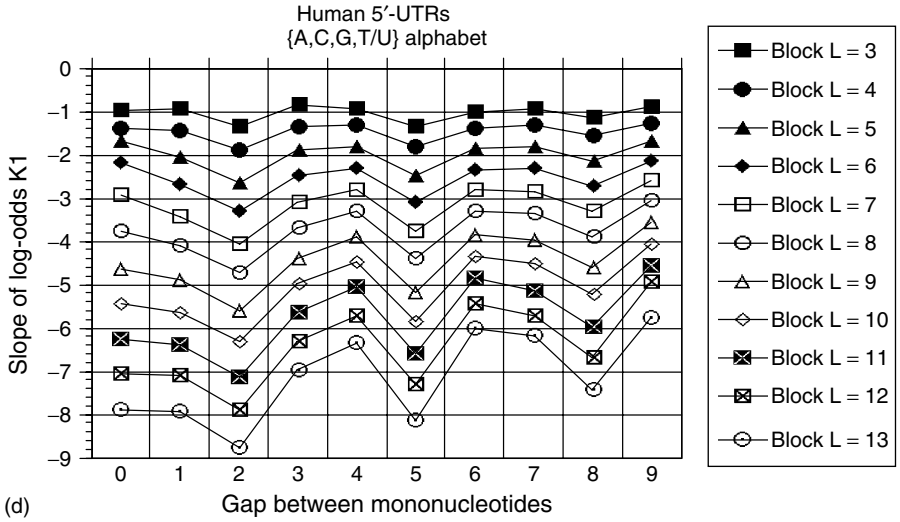
been transformed into biotechnology. On the other hand, the scientific remainder of molecular biology is in a desperate need of reconciliation with the rest of biology and with other fields of science. As far as computational molecular biology is concerned, research agendas that pertain to integration of sequence analysis with biology proper involve conceptual foundations of life sciences, methods



(c)



(d)

Fig. 6 (*Continued*)

of modeling biological systems, methods and concepts of data integration, as well as computer-assisted techniques of pragmatic inference. In this section, I briefly discuss selected general topics that seem to be representative of future research in computer-assisted systems biology.

6.1 Pragmatic and Semantic Theories of Information

The existing (Hartley-Shannon) theory of communication has been created for telecommunication systems and digital computers. Despite numerous proposals

stating otherwise, it does not seem to provide much new insight into molecular biology (it can be a useful source of statistical methods though). On the other hand, concepts of ''information,'' ''meaning,'' ''function,'' and ''organization'' seem to be integral parts of biology. If we are to comprehend the phenomenon of life despite our language limitations, we need to develop a theory that could handle these concepts. The need for a theory of information pertinent to biology has been already postulated in neurobiology and in developmental biology. Although such a need has not troubled molecular biologists quite yet, it begins to emerge as evidence accumulates for the role of ''epigenetic information'' in controlling gene expression and regulation.

6.2 Logic of Heuristic Reasoning

As most of us know, heuristic reasoning can be conclusive. Yet biologists face the problem of not being able to specify all the rules applied to derive conclusions. Nor are they able to list all assumptions on which those rules ought to operate. It seems that these inabilities are a reflection of the complexity of biological systems themselves. Biological phenomena are often represented by models that are still too complex to be described in a communicable manner. Further and further modeling is required until our observations can be communicated in a linguistically comprehensive way. The cascade of models gives us the advantage of creating ''communicable reality'' but does not help us to judge the evidence pertinent to ''real'' (i.e. not necessarily communicable) reality. On the contrary, the more advanced a model in a cascade is, the further is its ''distance'' (in terms of number of modeling steps) from the modeled system.

From a logical point of view, there are two problems here. First, we have no formal system of inference to judge *formal correctness* of observation sentences that have a variable true value (credibility) and that use ill-defined terms. Second, we have no formal system to judge the *material adequacy* of sentences derived from a ''distant'' model to the properties of modeled phenomena.

The problem of formal correctness seems to be solvable in principle. Progress in dealing with it can be noticed already in the fields of Artificial Intelligence (AI), Pattern Recognition (especially development of fuzzy mathematical techniques) and Situation Logic. In the near future, we can expect to have formal tools to derive plausible conclusions from imprecise premises. Or, at least, we will have the option of relying on a machine (i.e. reliable AI software) that will perform plausible reasoning for us.

As far as formal judgment of material adequacy is concerned, it is unlikely that the problem is addressable in all its generality. At least within mathematics, the celebrated Gödel theorem precludes such a possibility. However, informal (more or less educated common-sense) judgments of material adequacy are not only possible but all fields of science explore them.

6.3 Question of Measurement in Biology

The notion that only measurable properties of objects and phenomena belong to reality is a persistent legacy of neopositivism. For physicists, it means that

"real" things need to be viewed as systems of states with measurable observables (i.e. selected boundary conditions) assigned to those states. However, interpretation of biological activities in terms of microphysical phenomena will almost certainly lead to observables not known to physics so far. Moreover, preliminary evidence suggests that these new observables will be irreducible to the traditional (i.e. known) ones. How biologists will handle this measurement problem is not clear yet. Some authors suggest that perhaps it will be necessary for biologists to abandon the concept of states of the system as a foundation for modeling.

6.4 Convoluted Nature of Biological Systems

Complexity of biological systems is often described as a pivotal concept in systems biology. Unfortunately, this notion is terribly vague because there are over thirty different meanings in which it could be used and none of these meanings satisfactorily reflects the nature of living things. A satisfactory meaning (for "complex") should pertain to *functionally convoluted* systems (such as an organism, immune system, or ecosystem) that can be approximately described by several complementary models but cannot be adequately represented by a single model. This postulate of nonexistence of the largest model has several consequences such as:

1. Necessity to study pairs consisting of a modeler (usually a human) and the system to be modeled instead of the latter (i.e. modeled system) in isolation.
2. Promotion of the idea that functional organization of the system as a whole can be described by concepts and principles, which are independent from the properties of components.
3. The existence of general laws (or rules) that govern systems behavior (functioning) as a whole, which do not need to be derivable from the properties of the components of the system.

The foregoing general postulates of systems biology will likely lead to future research programs that will challenge causal reductionism (particularly the principle of upward causation) of the past explanations of emergence. Computer-assisted experimentation and model-making (theorizing) will without a doubt constitute a central methodology within these future paradigms.

Keywords

Enhancer
Cis-acting regulatory DNA element involved in transcriptional activation of genes. Enhancers are located distal to mRNA start site, function in either orientation and at either end of the gene, and bind specific proteins required for enhancer activity.

Promoter
Cis-acting regulatory DNA element involved in transcriptional activation of genes. Promoters are located proximal to the mRNA start site, exhibit orientation dependence, and bind specific proteins required for transcription.

TATA-box
A DNA sequence motif with the consensus TATA(A/T)A(A/T) that is commonly found 20- to 30-bp upstream of the mRNA start site in RNA polymerase II genes. The TATA-box binds TFIID, a transcription factor complex containing the TATA recognition protein, TBP (TATA-binding protein).

Preimplantation development in the mouse involves expression of about 11 000 genes, only a few hundred of which appear during the transition from maternal to zygotic gene expression. Transcription begins in most, if not all, mammals during the late one-cell stage (phase I), but expression of most zygotic genes is delayed until the 2-cell to the 16-cell stage, depending on the mammal. In mice, a small group of genes is expressed immediately after the first mitosis, while a larger group of genes is expressed during the subsequent G2-phase. Zygotic gene activation (ZGA) is delayed by a time-dependent mechanism (''zygotic clock'') that regulates both transcription and translation. It appears to involve posttranslational modification of RNA polymerases, translational control of maternal gene expression, developmental acquisition of chromatin-mediated repression, and the ability to alleviate this repression with sequence-specific enhancers. This delay allows remodeling of chromatin into a form that globally represses gene activity so that selected genes can then be activated in a temporally and spatially specific program. Some transcription factors (e.g. Sp1, TBP (TATA-binding protein)) function from oocyte to embryo, while others (e.g. Tead2, Oct4) are selectively expressed during ZGA. Dramatic changes also occur in DNA methylation. However, while DNA methylation has been linked directly to X-chromosome inactivation, genomic imprinting, and silencing of transposable elements, a direct role for DNA methylation in regulating gene expression during animal development has yet to be demonstrated. For example, the expression pattern of closely linked genes that are expressed in different cell types in adult animals is not determined by differential DNA methylation. DNA methylation appears to serve primarily to restrict gene expression by insuring that repressed genes remain silent.

1
Preimplantation Development

Preimplantation development in mammals encompasses the events that take place between fertilization (day 1) and formation of the blastocyst (day 4 in mice). In mice, fertilization activates the first of six to seven cell cleavage cycles over a four-day period; these cycles culminate in the formation of a blastocyst containing 64 to 128 cells, comprising two cell types (Fig. 1). The outer layer of cells comprises the trophectoderm that will form the placenta, while the inner cell mass consists of about 25 totipotent embryonic stem cells that will produce the embryo. The first round of DNA replication occurs in both the maternal and paternal pronucleus of the fertilized egg (or one-cell embryo). About 4 h later the first mitosis occurs to produce a two-cell embryo in which each ''zygotic nucleus'' contains a complete set of parental chromosomes. This cleavage event is rapidly followed by the second S-phase and expression of a small number of zygotic genes. Changes in totipotency of individual cells are first detected at the eight-cell stage, although clearly differentiated cells first appear at the blastocyst stage. Here the blastomeres of the embryo exhibit different cellular

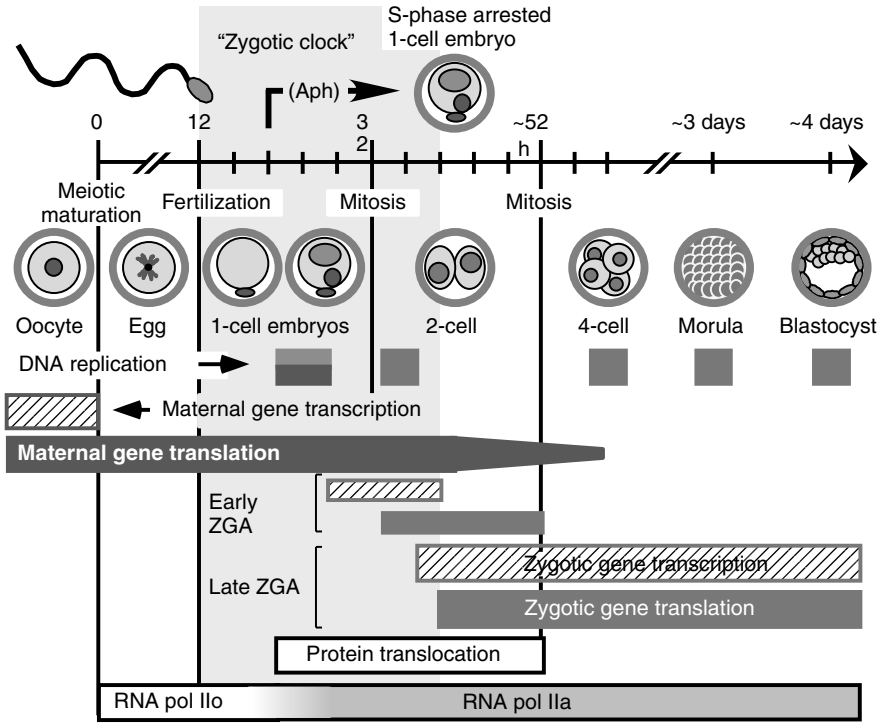

Fig. 1 Maternal to zygotic gene transition in the mouse. Maternal events are indicated in red, paternal events in blue, and zygotic events in green. Open bars apply to all three. Embryonic stem cells (''inner cell mass'') are indicated in yellow and trophectodermal cells in orange. Periods of transcription are indicated by hatched bars and translation is indicated by solid bars (see color plate p. xxi).

features that presumably lead to the formation of embryonic (inner cell mass) and extraembryonic (trophectoderm) lineages.

The series of specific morphological, biochemical, and molecular events that occur postfertilization, and that allow selected genes to be expressed, have been reviewed elsewhere.

2 Maternal to Zygotic Gene Transition

All of the genes in sperm and eggs are transcriptionally silent. Therefore, the first one or two cell-cleavage events and the activation of zygotic gene expression must rely on the reservoir of mRNAs and proteins stored in the egg. This transition from maternal to zygotic gene dependence and its associated changes in chromatin organization, gene expression, DNA replication, and cell division is a phenomenon characteristic of most, if not all, of the metazoa.

2.1 Timing

While transcription of the haploid genome in oocytes from all species stops when they mature into eggs, the extent of development and the time that elapses before transcription begins again after fertilization varies considerably among species. For example, before zygotic genes are activated in flies, the fertilized egg has undergone 10 nuclear divisions in 1.5 h, those from frogs have undergone 11 cell cleavages in 6 h, while those from mice have undergone only one cleavage event in 24 h. But even among mammals, the major onset of ZGA varies from the 2-cell stage in mice to the 4-cell stage in pigs, to the 8- to 16-cell stage in cows, sheep, and rabbits, presumably reflecting differences in the amount of one or more maternally inherited proteins or mRNAs. For example, mouse oocytes specifically express the protein ''zygote arrest 1'' that is required for progression of one-cell to two-cell embryos, and the protein ''matter'' that is required for progression beyond the two-cell stage. Rad51 and profilin also have been shown to be required for preimplantation development.

In the mouse, a growing oocyte that is arrested at diplotene of its first meiotic prophase transcribes and translates many of its own genes, thereby producing a store of proteins sufficient to support development to the eight-cell stage. When an oocyte matures into an egg, it arrests in the metaphase of its second meiotic division where transcription stops and translation of mRNA is reduced (Fig. 1). Fertilization triggers completion of meiosis and formation of a one-cell embryo containing a haploid paternal pronucleus derived from the sperm and a haploid maternal pronucleus derived from the oocyte. DNA replication begins after formation of the pronuclear envelopes, and occurs in each pronucleus from 10 to 16 hours postfertilization (hpf). The first mitosis occurs from 17 to 20 hpf to produce a two-cell embryo containing two diploid ''zygotic'' nuclei, each with a set of paternal and a set of maternal chromosomes.

Formation of a mouse two-cell embryo marks the transition from maternal to zygotic gene dependence (Fig. 1). Degradation of maternal mRNA is triggered by meiotic maturation and is ~90% complete in two-cell embryos, although translation of maternal mRNA continues into the eight-cell stage. Injection of plasmid DNA and transplantation of nuclei from two-cell stage embryos into one-cell embryos has

shown that late one-cell embryos are transcriptionally competent. Transcription of endogenous genes has also been detected in late one-cell mouse embryos where it begins at the end of S-phase. However, transcription-dependent protein synthesis does not begin until 2 to 4 h after completion of the first mitosis and the beginning of S-phase in two-cell embryos. Eight to ten hours later, during G2-phase of two-cell embryos, expression of zygotic genes increases in both amount and complexity.

Thus, ZGA has at least three recognizable phases: transcription without translation begins in late one-cell embryos (phase I), but transcription coupled to translation does not begin until the early two-cell stage in development (phase II), and robust transcription coupled to translation does not begin until the late two-cell stage (phase III). The existence of the first and third phases can be demonstrated clearly by injection of a plasmid-encoded reporter gene. The reporter gene is transcribed as soon as the one-cell embryo becomes transcriptionally competent, but it is not translated until the third phase of ZGA begins in late two-cell embryos. The second phase of ZGA is specific for a subset of zygotic genes. An early phase of ZGA consisting of a small group of genes appears to occur shortly after fertilization in all vertebrates; it is the late, robust phase of ZGA that is delayed to different extents in different species.

2.2 Genes

The available data suggest that 38 to 282 genes are specifically expressed during ZGA in mice, but only a few of these genes have been identified. Unfertilized mouse eggs contain 258 expressed sequence tags not found in adult mouse cDNA libraries.

Tab. 1 Genes expressed at the beginning of mouse development.

Gene	*Expression begins*	*Imprinting*
Hsp70.1	Early 2-cell	
Hsp68	Early 2-cell	
U2afbp	Early 2-cell	Paternal
eIF-1A	Early 2-cell	
Histone H1	Late 2-cell	
Oct4(Oct3)	Late 2-cell	
Tead2(TEF-4)	Late 2-cell	
cyclin-A	Late 2-cell	
Xist	Late 2-cell	Paternal
Sry	Late 2-cell	
Zfy	Late 2-cell	
3 Zn^{++} finger proteins	2-cell on; 8-cell off	
SRp20	2-cell to 4-cell	
Soggy	2-cell to 4-cell	
Snrpn	4-cell	Paternal

Analysis of cDNA expression libraries has identified 9718 to 11 483 genes expressed from the oocyte to the blastocyst stage, 798 to 1585 of which were not found elsewhere in the mouse. About 2.5% of newly synthesized proteins show a transient increase at the two-cell stage, and about 2.9% of unique expressed sequence tags in preimplantation embryos sharply increased in amount at the two-cell stage. Early *ZGA* genes (Fig. 1; Table 1) include heat shock genes, the translation initiation factor eIF-1A, a gene of unknown function, and three as yet unidentified proteins known as the "transcription-requiring complex." Another candidate, *Fas*, is a gene involved in apoptosis, whose mRNA appears to be expressed specifically at the two-cell stage in rats and the four-cell stage in humans. Examples of late *ZGA* genes include linker histone H1, transcription factors Oct-4(Oct-3) and Tead2(TEF-4), splicing factor SRp20, and *Sgy*, a gene of unknown function that

is closely linked to *Tead2* (Table 1). In the rabbit, ribosomal proteins S20 and L5, splicing factor p55, α-tubulin, a membrane transport protein VDAC2, and chaperonin are transcribed at the 8- to 16-cell stage (late ZGA). Expression of all of these genes is α-amanitin sensitive, and therefore presumed to be RNA polymerase II promoters.

Although less well characterized, RNA polymerase I and III dependent gene expression follows the same time course as RNA polymerase II dependent gene expression. Pol I, II, and III promoters are all recognized in late one-cell mouse embryos. Small nuclear RNAs U1 to U5, whose synthesis is dependent on pol II, as well as U6 whose synthesis depends on pol III, begin to accumulate at the two-cell stage in mice, concurrent with late ZGA. Similarly, U2 begins to accumulate at the 8- to 16-cell stage in cows. Changes in nucleolar morphology and nucleolar protein markers that provide a sensitive indicator of pol I dependent ribosomal gene expression are localized to the middle of the two-cell stage during mouse development, and the earliest stage at which rRNA synthesis has been detected is the mid to late two-cell stage. These results are consistent with the hypothesis that the high rate of ribosome assembly that begins in two-cell embryos requires the coordinate expression of pol I dependent rRNA synthesis and pol II dependent expression of genes for ribosomal proteins. In pigs and cows, rRNA genes are also activated at the four-cell and eight-cell stages, respectively, concurrent with late ZGA. Thus, it is clear that the transition from maternal to zygotic gene expression is a highly orchestrated sequence of events, spanning the first 40 h in the life of a fertilized mouse egg, and up to several days in other animals.

3 Zygotic Clock

In organisms that undergo rapid nuclear division after fertilization (e.g. amphibians, fish, echinoderms, flies), ZGA is determined by the ratio of nuclei to cytoplasm. Thus, ZGA occurs after a preset number of nuclear divisions have occurred, regardless of whether cellularization occurs (e.g. 13-cell cleavages in *Xenopus*; 10 nuclear divisions in the syncytium of *Drosophila*). However, in mice, ZGA is a time-dependent event that is delayed for about 24 hpf, and therefore begins after formation of a two-cell embryo (Fig. 1). The fact that ZGA is independent of DNA synthesis, cytokinesis, and the ratio of cytoplasm to nuclei allows ZGA to begin in S-phase-arrested one-cell embryos after they have advanced temporally to the ''two-cell stage'' (Fig. 1). The mechanism that determines when ZGA begins (referred to as the ''zygotic clock'') is not simply the time required to convert sperm and egg chromatin into a transcribable form, because it also regulates expression of injected plasmid-encoded genes utilizing RNA polymerase I, II or III dependent promoters. Therefore, the zygotic clock must involve delayed expression or activation of one or more transacting factors required for transcription and/or translation. Nevertheless, early *ZGA* genes are unique in that they begin translation immediately following the first mitosis, whereas plasmid-encoded genes are not translated until late ZGA, even though they are transcribed when injected into late one-cell embryos. Therefore, the zygotic clock regulates both transcription and translation of mRNA. Furthermore, the fact that plasmid-encoded genes are expressed during late ZGA reveals that

early *ZGA* genes are not simply more accessible to transcription factors than late *ZGA* genes; early ZGA genes are in some way predestined for immediate expression, perhaps by association with the transcription machinery.

3.1 Protein Translocation

Following fertilization, transcription factor Sp1, TATA-box binding protein, and RNA polymerase II all undergo a time-dependent concentration in the pronuclei, and both Sp1 mRNA and transcription factor activity increases markedly from the one-cell to the four-cell stage (Fig. 1). Both Sp1 and HSF1 are present in the pronuclei of one-cell embryos and are required for Hsp70.1 gene expression during early ZGA, but translocation of transcription factors to the nucleus cannot be the only component of the zygotic clock because, in contrast to ZGA, the translocation of these proteins does not require concomitant protein synthesis.

3.2 Protein Phosphorylation

In mice, rabbits, and frogs, the carboxyl-terminal domain (CTD) of the RNA pol II catalytic subunit is hyperphosphorylated and transcriptionally inactive in mature eggs (RNA pol IIo) (Fig. 1). Fertilization triggers dephosphorylation of the CTD into a hypophosphorylated form IIa that is required for initiation of transcription, and a reduced phosphorylated form IIe characteristic of somatic cells. Form IIa appears in late one-cell embryos prior to early ZGA in both mice and rabbits but form IIe is not observed until late ZGA. Late ZGA occurs in late 2-cell mouse embryos, at the 8- to 16- cell stage in rabbits, and at the midblastula transition in frogs. Like ZGA, these changes in phosphorylation require concomitant protein synthesis, and they may also account for the observation that ZGA in the mouse requires protein kinase activity. Posttranslational modifications of other proteins required for transcription, such as Sp1 and TBP, may also contribute to the zygotic clock mechanism, but this remains more speculative.

3.3 Translational Control

Maternal mRNA degradation is triggered by meiotic maturation and is about 90% completed in two-cell embryos, although maternal protein synthesis continues into the eight-cell stage. Nevertheless, some of the newly synthesized proteins are made from maternally inherited transcripts that are polyadenylated after fertilization and then translated. For example, newly synthesized histone H1, *Tead2*, Sp1, TBP, and cyclin-A are first translated from maternal mRNA in late one-cell or early two-cell embryos and then from zygotic mRNA during the late two-cell to four-cell stage. Such proteins are presumably required for chromatin remodeling and cell proliferation. As much as one-third of the mRNAs in two-cell embryos appear to contain a cytoplasmic polyadenylation element.

Despite the fact that transcription is first detected in G2-phase one-cell embryos, fertilized mouse eggs can delay expression of zygotic genes by uncoupling translation from transcription. Injection of plasmid-encoded genes revealed that the time courses for nascent mRNA accumulation from pol I, II or III dependent promoters are biphasic, with the second phase of transcription occurring just prior to late ZGA. An RNA polymerase II dependent gene can be transcribed prior to the

first mitosis, but it is not translated until zygotic gene expression begins (up to 15 h later). At this time, translation of RNA pol II transcripts becomes tightly linked to transcription (the second phase). Thus, the small amount of RNA synthesis that occurs in late one-cell embryos may simply represent premature transcription resulting from the appearance of transcription machinery before the parental genomes are completely masked by chromatin structure. In fact, one or more factors capable of repressing DNA transcription and replication are absent from one-cell embryos; they are produced just prior to ZGA. Thus, by delaying transcription and by preventing any transcripts that are made from being translated, the zygotic clock provides a window of opportunity for remodeling parental chromosomes in the absence of gene expression.

4
Developmental Acquisition of Transcriptional Regulation

4.1
Chromatin-mediated Repression

Transient expression from plasmid-encoded reporter genes and nuclear transplantation experiments have revealed the presence of transacting factors that can repress the activities of promoters and replication origins from 20- to >500-fold as fertilized mouse eggs develop into two-cell and four-cell embryos. The same appears to be true in rabbits, despite the fact that ZGA in rabbits does not occur until the 8- to 16-cell stage. While maternal nuclei in both oocytes and one-cell embryos exhibit this repression, the paternal pronucleus exhibits repression only when one-cell embryos develop beyond S-phase (Fig. 2). Sperm chromatin, which contains protamines but not core histones H2B and H3, becomes dispersed about 1 h after fertilization, and then within the following 7 h protamines are replaced by core histones and the DNA is condensed, the whole process being completed prior to DNA replication. Paternal pronuclei generally replicate more quickly than maternal pronuclei, which inherit a full set of histones from the oocyte and exhibit a different pattern of histone acetylation. Thus, paternal pronuclei may exhibit an ''unrepressed'' chromatin state while maternal pronuclei exhibit a ''repressed'' chromatin state.

This hypothesis is supported by observations that expression of microinjected genes in paternal pronuclei is ~5-fold greater than in maternal pronuclei, and inhibitors of histone deacetylase stimulate transcription in maternal pronuclei while reducing transcription in paternal pronuclei. The factor(s) responsible for this repression is absent from the cytoplasm of early one-cell embryos; it is not simply excluded from the paternal pronucleus. It is produced in the cytoplasm sometime between S-phase in a one-cell embryo and formation of a two-cell embryo where it can operate within any nucleus, regardless of its parental origin or ploidy. Repression increases as development proceeds from the two-cell to the four-cell stage. Such changes in chromatin structure could account for the fact that Hsp70.1 expression, which is constitutive in two-cell embryos, is repressed to a basal level during the four- to eight-cell stage.

These observations correlate well with changes in the synthesis and modification of chromatin-bound histones at the beginning of mouse development (Fig. 2). Oocytes, which can repress microinjected

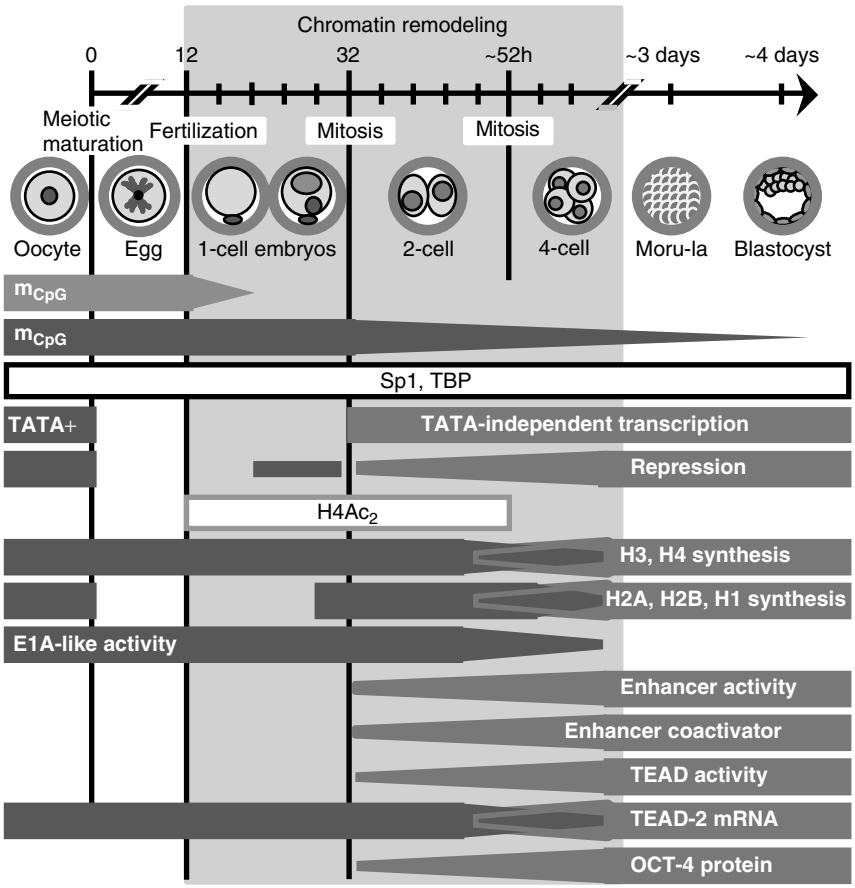

Fig. 2 Developmental changes affecting regulation of gene expression at the beginning of mouse development. These include changes in DNA methylation of the paternal and maternal genomes, changes in histone synthesis and modification that lead to chromatin-mediated repression, acquisition of chromatin-mediated repression, and acquisition of enhancer function. Some transcription factors such as Sp1 and TBP are ubiquitous. TATA-box function appears to be restricted to differentiated cells. Color coding and bar coding are the same as in Fig. 1 (see color plate p. xxii).

promoter activity, synthesize a full complement of histones; in addition, histone synthesis, which originates from mRNA inherited from the oocyte, can be observed up to the early two-cell stage. However, while histones H3 and H4 continue to be synthesized in early one-cell embryos, the synthesis of histones H2A, H2B, and H1 (proteins required for chromatin condensation) is delayed until the late one-cell stage, reaching its maximum rate in early two-cell embryos. Moreover, histone H4 in both one-cell and two-cell embryos is predominantly diacetylated (a modification that facilitates DNA transcription and chromatin assembly). Deacetylation toward the unacetylated and monoacetylated H4 population observed in differentiated

cells, such as the fibroblasts, begins at the late two-cell to four-cell stage. These changes correlate with the establishment of chromatin-mediated repression during formation of a two-cell embryo as well as the increase in repression from the two-cell to four-cell stage, where accumulation of linker histone H1 and deacetylation of core histones are observed. The arresting of development at the beginning of S-phase in one-cell embryos prevents both the appearance of chromatin-mediated repression of transcription in paternal pronuclei and synthesis of new histones. The pattern of hyperacetylated histones throughout the nuclei also changes as embryos progress from the one-cell to the four-cell stage, but the significance of these changes remains speculative.

Similar changes in histone composition occur during frog development. Histone H4 is stored in a diacetylated form in *Xenopus* eggs and then progressively deacetylated after ZGA begins at the blastula stage. Histone deacetylase inhibitors can then induce expression of specific genes. The type of linker histone changes from the maternal histone H1 variant (B4) at the midblastula transition to the somatic histone H1 variant at the end of gastrulation, resulting in specific repression of oocyte 5 S RNA gene expression. The initial activation of H1 synthesis occurs entirely by activation of maternal transcripts that then disappear by the early gastrula stage. Thus, the induction of chromatin-mediated repression may be a common feature of the maternal-to-zygotic gene transition in all metazoa.

Oocytes and early embryos of many nonmammalian species lack the somatic cell form of the linker histone H1; somatic H1 was originally believed to be absent from mouse and bovine oocytes and then first expressed at the four- to eight-cell stage of development. mRNA for H1 variants could be detected in these cells, and $H1^0$ protein could be detected in oocytes, suggesting that $H1^0$, rather than somatic H1, was present during ZGA. However, the incorporation of radiolabeled amino acids revealed that somatic H1 is indeed synthesized in mouse oocytes and in preimplantation embryos starting from the late one-cell stage. Moreover, improved methods of immunological detection confirmed that somatic H1 is present throughout this period, although it is not present on maternal metaphase II chromatin. Upon formation of pronuclear envelopes, somatic H1 is rapidly incorporated onto maternal and paternal chromatin, and the amount of somatic H1 on embryonic chromatin steadily increases to the eight-cell stage. These data suggest that the major changes in histone H1 that accompany ZGA involve changes in the amount and location of somatic H1 rather than in selective expression of H1 variants. Nevertheless, a maternally derived H1 variant (H1oo) that bears significant homology with the oocyte-specific *Xenopus* B4 histone and sea urchin cs-H1 histone is specifically expressed in mouse oocytes – one-cell and two-cell embryos – but disappears by the four- to eight-cell stages. Thus, while somatic H1 appears responsible for global changes in chromatin structure, selected genes may be regulated by oocyte-specific H1 variants.

Manipulation of the ratio of chromatin-bound proteins to DNA can alter ZGA. For example, injection of somatic cell histone H1 into mouse one-cell embryos retards the onset of RNA polymerase II transcription in late one-cell embryos (phase I of ZGA), presumably by increasing chromatin condensation, while injection of HMG-1 (a protein that binds AT-rich sequences and that can modulate

gene expression) advances it. Similarly, the depletion of HMG-14 and HMG-17 – two chromosomal proteins that generally stimulate transcription – by injecting one-cell embryos with antisense oligonucleotides delays, but does not prevent, preimplantation development. The fact that these experimental insults did not prevent development of one-cell embryos into blastocysts suggests that cells recover by degrading injected proteins and antisense oligonucleotides.

Global inhibition of ZGA by H1 does not affect all genes, because injection of histone H1 into one-cell embryos does not inhibit expression of the ''transcription-requiring complex'' of proteins (phase II of ZGA). This may also explain why neither the injection of H1 nor of HMG-1 had a significant effect on the development of one-cell embryos. Nevertheless, coinjection of histones H1, H2A, H2B, H3, and H4 together with a plasmid-encoded reporter gene into the paternal pronuclei of one-cell embryos can recreate the behavior observed when plasmid-encoded genes are injected into the nuclei of two-cell embryos: the injected gene is repressed and this repression can be relieved by including either a functional enhancer or histone deacetylase inhibitors. In these experiments, the effect of H1 was to reduce the amount of core histones needed to repress gene expression. Thus, chromatin-mediated repression that can be relieved by embryo-responsive enhancers (phase III of ZGA) can be made to occur in one-cell paternal pronuclei simply by assembling the DNA into somatic cell chromatin.

4.2 Enhancer Function

Direct evidence that repression of promoter activity at the beginning of mouse development is mediated through chromatin structure comes from the effects of inhibitors of histone deacetylases and enhancers on gene expression. Repression can be relieved either by treating cells with inhibitors of histone deacetylase or, in cleavage stage embryos (two-cell embryos to morula), by linking the promoter or replication origin to an embryo-responsive enhancer. Inhibitors of histone deacetylase, such as trichostatin A and sodium butyrate, increase the fraction of hyperacetylated core histones and thereby stimulate transcription from specific genes. This is consistent with the fact that transcriptionally active eukaryotic genes are generally associated with acetylated core histones. In mouse one-cell embryos, butyrate can stimulate promoter activity on genes injected into the maternal pronucleus (''repressed''), but not into the paternal pronucleus (''unrepressed''). Thus, stimulation is caused by changes in chromatin structure of the injected plasmid and not by increased synthesis of transcription factors. If the latter were the cause of stimulation, the butyrate would affect both pronuclei.

Enhancers can substitute for butyrate in stimulation of promoter activity, but only after formation of a two-cell embryo (Fig. 2). Enhancers are inactive in oocytes and one-cell embryos even when the appropriate sequence-specific activation protein required for enhancer activity is present (e.g. GAL4:VP16, Tead, Sp1), because an enhancer-specific coactivator activity is not produced until ZGA. This coactivator activity works on most, if not all, enhancers and likely represents one or more of the proteins identified in both yeast and mammalian cells that appears to mediate the interaction of upstream sequence-specific transcription factors with the RNA pol II complex.

In vitro, enhancers do not stimulate transcription unless the DNA substrate is organized into chromatin. *In vivo*, enhancers have little, if any, effect on promoters injected into two-cell embryos cultured in butyrate. Therefore, the primary role of enhancers is not simply to provide additional transcription factors to facilitate formation of an active initiation complex, but to relieve repression of weak promoters by chromatin (Fig. 3). Direct proof for this hypothesis comes from coinjection of purified histones and a plasmid-encoded reporter gene into the paternal pronuclei of one-cell embryos. Acquisition of chromatin-mediated repression of the injected promoter and subsequent relief of this repression either

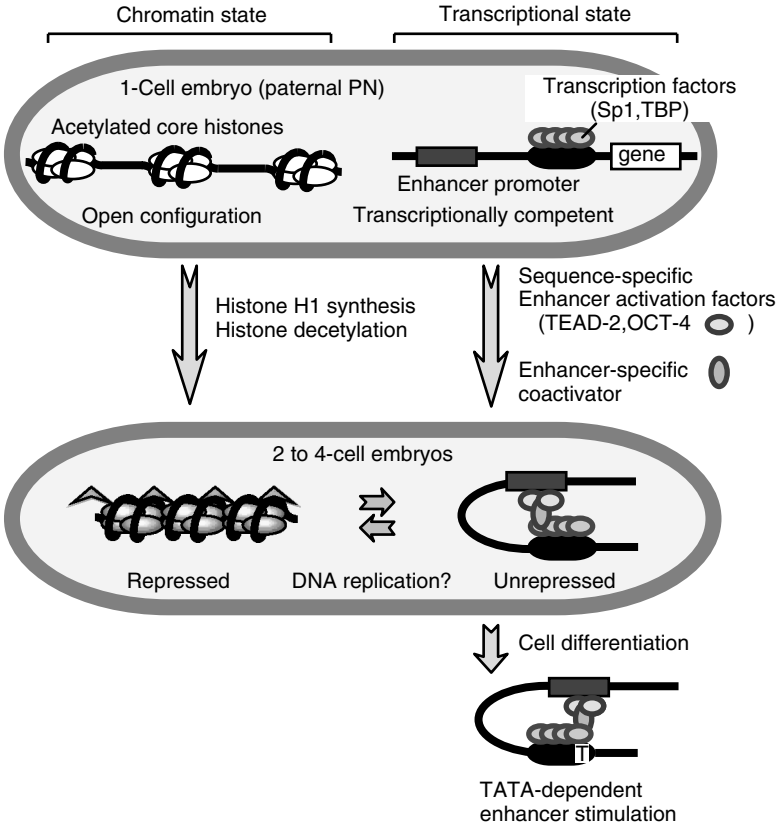

Fig. 3 Relationships between chromatin structure, promoter/enhancer activity and DNA replication during the maternal-to-zygotic gene transition in the mouse. Chromatin in the paternal pronucleus is in an open configuration that does not suppress promoter activity. Formation of a two-cell embryo is accompanied by changes in chromatin structure that repress promoter activity. This repression can be relieved by enhancer activity that requires sequence-specific-enhancer binding proteins such as Tead2 or Oct-4, and an as-yet-unidentified enhancer-specific coactivator, all of which first become available during ZGA. DNA replication may facilitate activation of some genes. Cell differentiation is accompanied by the need for a TATA-box element in the promoter to enable enhancers to function.

by functional enhancers or by histone deacetylase inhibitors occurred at a specific ratio of histones to DNA. The extent of the enhancer-mediated stimulation was found to be inversely related to the acetylation status of the histones and dependent on the developmental acquisition of the enhancer-specific coactivator activity.

The results described above reveal that the ''zygotic clock'' delays ZGA in mice by preventing the bulk of transcription and translation until two-cell embryos have entered G2-phase (36 to 40 hpf). By that time, chromatin-mediated repression has begun and the ability to use enhancers has been acquired. The net result is a global repression of mammalian gene expression, thus permitting specific genes to be activated at specific times and in specific tissues through the expression of specific promoter and enhancer activation proteins that activate their promoter/enhancer, as well as by specific proteins that relieve chromatin-mediated repression (e.g. histone acetyltransferase, GAGA, SWI/SNF complex).

4.3 DNA Replication

As discussed above, the ability of chromatin structure to repress DNA transcription or replication, and the ability of enhancers to relieve this repression first appear in mouse development with formation of two-cell and four-cell embryos. However, enhancers alone cannot always relieve chromatin-mediated repression. Once a repressed state is formed, it may be necessary for DNA to replicate in order to reprogram itself into a transcriptionally active state (Fig. 3). When DNA is injected into either pronucleus of one-cell embryos, and the injected embryo then undergoes mitosis to form a two-cell embryo, the injected promoter becomes ''irreversibly'' repressed, in that neither enhancers nor butyrate can restore its activity. This is not due to loss of plasmid DNA from the injected pronucleus during mitosis, because repression is reversible when the injected pronucleus is transplanted to a two-cell embryo that then undergoes mitosis. Therefore, something happens to DNA between completion of S-phase in a one-cell embryo and formation of a two-cell embryo, which prevents activation of injected genes while allowing embryonic genes to undergo ZGA. One explanation is that plasmid DNA does not replicate when injected into mouse embryos unless it contains a viral replication origin, whereas the genome of a one-cell embryo undergoes one round of replication prior to early ZGA and two rounds prior to late ZGA. DNA replication may be required to restore the newly remodeled zygotic genome to a transcriptionally competent state. Chromatin assembly in one-cell embryos occurs in the absence of at least one factor required for enhancer function; this factor does not appear until the two-cell stage. Therefore, if chromatin-mediated repression begins in late one-cell embryos, before enhancers are functional, DNA replication may be required to disrupt the repressed state so that appropriate transcription factors can bind. Conversely, once an enhancer has acted to prevent repression of its adjunct promoter, the resulting transcription complex may remain active until replication again allows reprogramming. Thus, the fraction of genes encoded by plasmid DNA that are ''on'' or ''off'' will depend on the relative amounts of repressor *versus* enhancer activation proteins present at the time of injection.

Recent evidence provides some support for this hypothesis. Complete inhibition of DNA synthesis in one-cell embryos with

aphidicolin (a specific inhibitor of replicative DNA polymerases) does not prevent early ZGA, but it does reduce the amount of transcription observed by nearly one-third. It also inhibits transcription of the eIF-4C gene by nearly one-half and the synthesis of the ''transcription-requiring complex'' (TRC) of proteins by ~90%. These results suggest that expression of some of the early *ZGA* genes is dependent on prior replication of some or all of the genome. The effect, however, is overestimated by measuring TRC synthesis, because inhibition of DNA replication in one-cell embryos is accompanied by a general decrease in total protein biosynthesis that accompanies the decrease in TRC synthesis. Nevertheless, for integrated transgenes, enhancer activity first occurs at the two- or four-cell stage, but only after completion of DNA replication., suggesting that DNA replication is required to relieve chromatin repression. Thus, the possibility that disruption of chromatin structure by DNA replication permits reprogramming of gene expression remains an attractive hypothesis.

4.4 TATA-box Function

Once ZGA begins, the requirements for transcription can differ from those observed at later stages in development. In yeast, proteins binding to upstream activator sequences can facilitate binding of TBP to the TATA-box, thus accelerating transcription. Moreover, the TATA-box element common to many RNA pol II promoters appears to be required only when a promoter is stimulated either by an upstream enhancer or by a transacting factor equivalent to herpesvirus ICP4 or adenovirus E1A proteins. However, prior to cell differentiation, enhancer stimulation is observed in the absence of TATA-box cell differentiation. This would imply that the TATA-less promoters that drive transcription of typical housekeeping genes can be stimulated selectively in cleavage stage embryos, but not in differentiated cells (Figs. 2, 3). In fact, oocytes are unique in that they express an E1A-like activity that may serve to stimulate genes in place of enhancer activity (Fig. 2).

4.5 DNA Methylation

The bulk of DNA methylation in eukaryotes consists of 5-methyl cytosines within CpG dinucleotides. In mammals, three families of DNA methyltransferases (Dnmt 1, 2, and 3) have been identified. Dnmt-1 is the enzyme responsible for maintaining DNA methylation patterns during DNA replication by converting hemimethylated CpG dinucleotides into fully methylated CpG dinucleotides. Dnmt-3 is involved in *de novo* methylation. The role of Dnmt-2 is not yet known. In addition to these enzymes, five proteins have been identified that bind to ^{m}CpGs (MeCP1 and 2, and MBD proteins 1 to 4; MBD-2 is the ^{m}CpG-binding protein in the multiprotein complex MeCP1). These proteins are associated with ^{m}CpGs and are believed to be involved in gene silencing.

Clearly, DNA methylation is required for proper embryonic development. For example, loss of Dnmt-1 results in embryonic stem (ES) cells that proliferate normally with their DNA highly demethylated but that die upon differentiation, with the consequence that embryos lacking this enzyme are delayed in development, and do not survive past midgestation. Similarly, mice lacking MBD-3 die during early embryogenesis. The precise reasons for these effects, however, and the identity of

the factors that control methylation pattern dynamics during gametogenesis and early development, are largely unknown.

Global methylation patterns are erased in primordial germ cells and then reestablished in sex-specific patterns in mature male and female germ cells. There is an additional wave of demethylation during preimplantation development, although some sequences, notably certain imprinted genes, retain gametic methylation patterns at all stages. While primordial germ cells are highly methylated when compared to somatic cells, both male and female primordial germ cells undergo global demethylation that is completed by embryonic day 13 or 14. Both imprinted genes and single-copy genes are demethylated at this stage. Whether this demethylation step involves active or passive demethylation is unknown. However, when embryonic germ cells are fused with somatic cells, somatic nuclei undergo demethylation, suggesting the existence of factor(s) in germs cells that confer demethylation in ''trans.'' In the male germ cells, remethylation takes place at the prospermatogonia stage (E15/16 onward), which precedes the mitosis/meiosis step. In contrast, remethylation of female primordial germ cells occurs during the growth of oocytes in young animals. These demethylation/remethylation steps are thought to be required in order to reset the imprinting cues and reprogram epigenetic modifications in germ cells.

Demethylation and remethylation also take place during embryogenesis (Fig. 2). The paternal genome is actively demethylated within the first 8 h after fertilization, prior to DNA replication. Although the nature of the demethylating mechanism is not yet clear, it would appear that chromatin remodeling of sperm DNA exposes it to enzymes that can demethylate it, while the chromatin structure of oocyte DNA protects it from demethylation. In contrast to the paternal genome, the maternal genome is passively demethylated by DNA replication in the absence of Dnmt-1 activity, as cells undergo cleavage from the 2-cell to the 32-cell (morula) to blastula stages. Dnmt-1 is localized in the cytoplasm during preimplantation development. CpG methylation activity returns after implantation, and confers methylation patterns similar to what is observed in somatic cells.

DNA methylation patterns associated with imprinted genes appear to be shielded from demethylation during preimplantation development. Part of the mechanism that prevents loss of these methylation imprints involves a novel form of Dnmt-1. Mouse oocytes and preimplantation embryos lack Dnmt1, but they express a variant called Dnmt-1o. After fertilization, this extremely abundant form of Dnmt1 is relegated to the cytoplasm until the eight-cell stage when, for a single cell cycle, it enters the nucleus. Dnmt-1o is then excluded from the nucleus in subsequent cell cycles until postimplantation day eight.

Although genomic methylation patterns are established normally in Dnmt-1o-deficient oocytes, embryos derived from such oocytes show a loss of allele-specific expression and methylation at certain imprinted loci. Experiments with mice lacking functional Dnmt-1o suggest that the maintenance of imprinted methylation is critically dependent on the role of this enzyme during the eight-cell stage. Here the absence of Dnmt-1o results in failure of the newly replicated paternal strand to become methylated. Subsequently maintenance methylation occurs normally, but there is a 50% reduction of methylation on newly replicated paternal alleles. This heritable change results in some cells having

either differentially methylated parental alleles or ones that are unmethylated. Thus, Dnmt-1o is not required for the establishment of maternal genomic imprints, but instead appears to be required specifically for maintenance methylation of imprinted loci.

While CpG methylation has been directly linked to a number of biological phenomena including X-chromosome inactivation, imprinting, and silencing of repeat sequences and retroviruses, its direct role in regulating gene expression has yet to be demonstrated. Methylation of CpG dinucleotides is commonly correlated with a loss of gene expression both *in vivo* and *in vitro*. Nevertheless, the absence of a change in the DNA methylation pattern of several tissue-specific genes during early mouse development has led to the hypothesis that CpG methylation is a consequence of the absence of transcription rather than the cause, and thereby serves to insure that repressed genes remain silent.

What is the purpose of these demethylation/remethylation events in preimplantation embryos? One general consequence of global demethylation is to remove one of the major obstacles to the binding of proteins to DNA. These proteins may include repressor proteins whose binding is abrogated by methylation. With the exception of the five proteins known to bind specifically to ^{m}CpG dinucleotides, the affinity for DNA of all other DNA binding proteins appears to be reduced by methylation of their DNA binding sites. Thus, demethylation may facilitate remodeling of sperm chromatin into somatic cell chromatin in one-cell embryos, and it may allow more subtle remodeling to take place in both paternal and maternal genomes during the preimplantation period.

DNA methylation may also prevent specific genes from being activated during ZGA, because one characteristic of genes that are destined to be transcribed during ZGA appears to be the absence of DNA methylation at their regulatory regions in sperm. For example, the regulatory regions of the *Sgy* and *Tead2* genes (Table 1) are not methylated in either sperm or oocytes. A number of genes that are expressed during ZGA are expressed only from the paternal allele (Table 1), and in the case of U2afbp-rs and Xist, these alleles enter development in an undermethylated state. DNA methylation patterns associated with imprinted genes appear to be shielded from demethylation during preimplantation development. In contrast, the tissue-specific mouse skeletal α-actin promoter is fully methylated in the sperm and essentially unmethylated in the oocyte.

4.6 Differential Gene Expression

The average spacing of genes in human cells has been estimated to be 85 kb. However, the number of closely spaced, divergently expressed genes is surprisingly high. In some cases, two closely spaced genes are transcribed in the same cell (coordinately expressed), whereas in other cases, only one of the two genes is transcribed in a particular cell type (differentially expressed). A common feature of these bidirectional loci is the presence of a CpG island, suggesting that DNA methylation may regulate their expression during animal development. However, one detailed analysis of such a locus has revealed (1) that differential expression of closely spaced genes is developmentally acquired, and (2) that DNA methylation restricts, but does not dictate, differential gene expression during mouse development.

Tead2 is the only member of the *Tead* gene family of transcription factors that is expressed in mouse embryos during the first seven days of development suggesting that it plays a unique role at the beginning of mammalian development, when it is presumed to be responsible for the ability of preimplantation mouse embryos to utilize Tead-dependent promoters and enhancers. In adult animals, *Tead2* continues to be expressed to varying extents in most cell types. Soggy (*Sgy*) is a novel single-copy gene whose mRNA start site is located only 3.8-kb upstream of the *Tead2* mRNA start site. The function of *Sgy* is unknown, but it is presumed important because its expression pattern in the adult is restricted to lymphocytes and pre-spermatocytes, and it is partially homologous to the Dickkopf gene family, potential effectors of the Wnt signaling pathway. Since *Tead2* and *Sgy* are transcribed in opposite directions, their regulatory elements lie in close proximity. In fact, the same locus is found in humans on chromosome 19q13.3, except that the two mRNA start sites are separated by only 1.5 kb. Both mRNA start sites lie within CpG islands.

Both *Sgy* and *Tead2* are expressed concurrently during zygotic gene activation in mouse preimplantation embryos and in embryonic stem cells where their regulatory regions are unmethylated. However, with the onset of cell differentiation and DNA methylation, cells express one gene or the other, but not both. This differential gene expression is restricted by DNA methylation, because neither gene is expressed in cells in which its regulatory region is methylated, and *Sgy* expression in permissive cells is inversely related to the extent of methylation in the *Sgy* regulatory region. Consequently, a sharp transition between unmethylated and methylated DNA marks the upstream boundary of each active promoter. Moreover, recovery of *Sgy* expression is accompanied by demethylation of the *Sgy* promoter. Nevertheless, DNA methylation *per se* does not determine expression at the *Sgy*/*Tead2* locus, because some cells do not express one of these genes even when its regulatory sequences are unmethylated. Thus, while DNA methylation can restrict gene expression during mammalian development, it is not the primary regulatory mechanism. Therefore, the developmental acquisition of differential gene expression must depend primarily on the presence of gene-specific activators and repressors.

Keywords

Biological Weapons
Microbial agents or their toxins with the potential of causing mass casualties.

Biological Weapons Convention (BWC)
Convention on the prohibition of development, production, and stockpiling of biological and toxin weapons and their destruction.

Bioterrorism
The intentional use of a pathogen or biological product to cause harm to humans, animals, plants or other living organisms to influence the conduct of government or coerce a civilian population.

Bioterrorism Preparedness
Preparedness of the public health infrastructure, the political/administrative system, and the health care system against bioterrorism threats and events.

Biowarfare
The intentional use of microbial agents or their toxins in warfare.

During the Great Depression, Hans Zinser, a bacteriologist and historian wrote that ''Infectious Disease is one of the few genuine adventures left in the world.'' Emphasizing that this has remained so, Madeline Drexler in 2002 pointed out that ''Modern adventurers like to up the *ante*, but even the most extreme sports wouldn't produce the adrenaline of a race against pandemic influenza or a cloud of anthrax at the Super Bowl. In the field of infectious disease, reality is stranger than anything a writer could dream up. The most menacing bioterrorist is Mother Nature herself.'' Accepting nature as the constant reservoir and source of infectious agents puts bioterrorism preparedness in the more appropriate context of preparedness against the infectious agents. By their very nature, infectious agents have the capability to spread fast and cross national borders. The course of human history has frequently been altered by epidemics that swept unchecked across continents, claiming more lives and creating more social devastation than wars. With the ease and speed of global travel now, the spread of infectious agents happens faster than ever before. An example of this is the ongoing (at the time of this writing) outbreak of Severe Acute Respiratory Syndrome (SARS). The past and the present efforts of the World Health Organization and many national agencies to strengthen global preparedness for defense against infectious disease threats is part and parcel of bioterrorism preparedness. Infectious agents have been, and in the foreseeable future will remain, potential tools of mass casualties. Historically, outbreaks (wars) of microbial species against the human species have killed far more people than war itself. Examples include: (1) death of 95% of Pre-Columbian Native American populations by diseases like smallpox, measles, plague, typhoid, and influenza; (2)

death of 25 million Europeans (a quarter of the population) caused by Bubonic Plague in the fourteenth century; and (3) 21 million deaths due to the influenza pandemic of 1918–1919. Worldwide, naturally occurring infectious diseases remain the major causes of death. In the United States, the impact of a number of very virulent biological agents and/or their toxins has been drastically reduced because of a very accessible health care system and excellent public health infrastructure. Still, a substantial number of people (approximately 170 000) die each year from infectious diseases. The travel and trade necessary for economic globalization, continued potential for transmission of infectious agents from animals to humans, and large populations living in proximity in major urban areas of the world, make disease outbreaks a major threat. The resistance of common pathogens to the available antimicrobial agents adds significantly to the threat. Advances in public health, diagnostic, and pharmacological interventions are needed to protect the population from emerging and reemerging infectious diseases, including those related to potential bioterrorism events.

1 Biowarfare versus Bioterrorism

The intentional use of microbial agents in warfare dates back to days when neither the pathogens nor the host pathogen interactions were known. It is important to recognize that biological agents have been used in warfare from antiquity to the present. The intentional use of living organisms or infected materials derived from them has occurred over centuries during war and ''peace'' time by armies, states, groups, and individuals. One of the first recorded uses of a biological agent in the war was in 184 B.C. The Carthaginian soldiers led by Hannibal used snakes in the battle against King Eumenes of Perganium and achieved a victory. A strong association was made between foul odors and disease, well before the development of the germ theory of disease, and many early civilizations employed crude forms of biological warfare. As early as 300 B.C., the Greeks polluted the wells and drinking water supplies of their enemies with animal corpses. The same tactics were used later by the Romans and Persians. The bodies of dead soldiers as well as animals were used to pollute wells during a battle in Italy in 1155. Pollution (poisoning) of potable water was used as an effective and calculated method of gaining advantage in warfare throughout the Classical, Medieval, and Renaissance periods. In the more modern times, General Johnson used the bodies of sheep and pigs to pollute drinking water at Vicksburg during the US Civil War.

The use of catapults and siege machines during medieval times introduced new technology to biological warfare. In 1346, the attacking Tartar force experienced an epidemic of plague during the siege of Kaffa (now Feodosia, Ukraine). They catapulted the cadavers of their deceased into the city to initiate a plague epidemic. An outbreak of plague did occur followed by the retreat of defending forces and the conquest of Kaffa. It is thought that this contributed to the second plague pandemic as the ships carrying

plague-infected refugees and rats sailed to Constantinople, Genoa, Venice, and other Mediterranean ports.

The inhabitants of Central and South America were decimated by smallpox and measles that accompanied the Spanish Conquistadores. In 1763, the introduction of a specific disease, smallpox, as a weapon in the North American Indian Wars became a significant milestone in the history of biological warfare. This adaptation of Trojan horse use was employed by Captain Ecuyes, on June 24, 1763, by handing blankets and a handkerchief from the smallpox hospital to the Native Americans. Sir Jeffery Amherst, Commander of British forces in North America, had suggested the deliberate use of smallpox to ''reduce'' Native American tribes hostile to the British.

The development of the science of bacteriology in the nineteenth century expanded the scope of potential biological warfare agents. *Bacillus anthracis* was the first specific agent attributed to human disease when Robert Koch fulfilled his own ''postulates'' concerning this organism in 1877. During World War I, Germany was accused of using cholera in Italy and plague in St. Petersburg in 1915. There is evidence that Germany used glanders and anthrax organisms to infect horses, mules, and cattle (1916–1918). These covert operations were conducted on neutral trading partners of the allies to infect livestock and to contaminate animal feed to be exported to allied forces.

The modern era of biological weapons development began immediately before and during World War II. The Japanese released fleas infected with plague in Chinese cities in the 1930s and 1940s. Between 1940 and 1942, Japanese unit 731 dropped bombs containing up to 15 million plague-infected fleas on two Chinese cities – Quxian and Ning-hsien, resulting in thousands of deaths. Water supplies and food items were contaminated with *B. anthracis*, Cholera, Shigella, Salmonella, and *Yersinia pestis*.

The origin of the biological weapons program of the former Soviet Union dates back to statements by Lenin. Although experimental work was started in the late 1920s, the modern era was ushered in only with the postwar military building programs. The Allied Biological Weapons program had shifted from the British research on anthrax (and the development of the World War II anthrax cattle cake retaliation weapon) to a large US-based research, development, and production capability. The US military had accepted seven types of classified agents and could produce 650 tons of an agent per month at plants such as the one at Pine Bluff in Arkansas. This offensive program was unilaterally abandoned in 1969, giving impetus to the creation of the Biological and Toxin Weapons Convention. The Soviet Union signed the Convention at its inception in 1972. Unfortunately, the number of countries engaged in biological weapons experimentation grew from 4 in the 1960s to 11 in the 1990s. It is estimated that at least 10 nations and possibly 17 possess biological warfare agents. Of the seven countries listed by the United States Department of State as sponsoring international terrorism, at least five are suspected to have biological warfare programs. Nations and dissident groups have the access to the skills needed to selectively cultivate some of the most dangerous pathogens and to deploy them as agents of biological terrorism and war.

Iraq's biological weapons program dates back to at least 1974 and has been carried out secretly after the Biological and Toxin Weapons Convention had been signed. In

1995, Iraq confirmed that it had produced and deployed bombs, rockets, and aircraft spray tanks containing *B. anthracis* and botulinum toxin. In 1973, the Soviet Politburo formed the organization known most recently as *Biopreparat*, designed to carry out offensive biological weapons programs concealed behind civil biotechnology research. In January 1991, the first ever visit to Biopreparat facilities was undertaken by a Joint United Kingdom/United States technical team. By the mid-1990s, substantial changes took place within Biopreparat, and a concerted effort is underway to help the Russians civilianize these former biological weapons research and development establishments. The current capability of the old Russian Ministry of Defense sites remains largely unknown. The status of one of Russia's largest and most sophisticated former bioweapons facilities called *Vector* in Koltsovo, Novosibirsk, is of concern. The facility housed the smallpox virus as well as work on Ebola, Marburg, and the hemorrhagic fever viruses (e.g. Machupo and Crimean-Congo). A visit in 1997 found a half-empty facility protected by a handful of guards. No one is clear where the scientists have gone. The confidence that this is the only storage site for smallpox outside the Centers for Diseases Control and Prevention is lacking.

2 Chronology of Biodefense Actions

1910–1920s–The first use of chemical and biological weapons in combat led to efforts to ban their use.

1925–The use of biological and chemical weapons in war was prohibited by The Geneva Protocol. The United States signed but failed to ratify the treaty. The treaty contained no provision for verifications and inspection.

1950s–1970s–The Soviet Union and United States built arsenals of biological and chemical weapons. International pressures mounted to draw up new treaties to curb such weapons.

November 25, 1969–President Richard M. Nixon unilaterally renounced the use of biological weapons in war by the United States and restricted research to immunization and safety efforts. Three months later, he extended the ban to include toxins. The United States Army Medical Research Institute for Infectious Diseases (USAMRIID) at Fort Detrick, Maryland, was established to conduct unclassified research on safety against potential agents of bioterrorism.

1972–Convention on the prohibition of the development, production, and stockpiling of bacteriological (biological) and toxin weapons and their destruction opened for signature at Washington, London, and Moscow on April 10, 1972.

1975–The United States Congress ratified the Biological and Toxin Weapons Convention (BWC) as well as the 1925 Geneva Protocol on January 22, 1975. The Biological and Toxin weapons Convention entered into force on March 26, 1975.

There are now 143 state parties to the convention and an additional 18 signatories. Article VI of the Convention has proved to be an inadequate mechanism for actions against noncompliance.

1980s–Arms control initiatives failed to curb biological and chemical weapons proliferation.

1984–President Reagan's administration presented a draft treaty to ban the production and storage of chemical

weapons to the Conference on Disarmament in Geneva.

1990s–Concerns over exposure to chemical and biological weapons during the Persian Gulf War increased support for international treaties.

May 13, 1991–Shortly after the Allied victory against Iraq, President George Bush announced that the United States will renounce the use of chemical weapons for any reason, and an international treaty banning them took effect.

April 1992–Russian President Boris N. Yeltsin declared that Russia's biological weapons program is being discontinued.

January 1993–President George Bush signed the Chemical Weapons treaty at the convention, banning the production and use of chemical weapons.

January 7, 1997–The Presidential Advisory Committee on Gulf War Veterans' illnesses found no conclusive evidence linking Gulf War Syndrome to chemical or biological weapons.

April 15, 1997–New regulations aimed at limiting access to chemicals and pathogens that could be made into weapons went into effect under the 1996 Antiterrorism and Effective Death Penalty Act.

April 29, 1997–The Chemical Weapons Convention (CWC) went into effect. It has more than 160 signatories and 65 ratifications.

July 25, 2001–The United States rejected a protocol to strengthen the Biological Weapons Convention as well as the whole approach to it. As in the Chemical Weapons Conventions (CWC), a strong bioweapons protocol could add to the deterrence of bioweapons, which are a much greater threat than chemical weapons.

November 19, 2001–Fifth BWC Review Conference was held.

3 The Concept of "Bioterror"

As the ease of cultivating microorganisms increased and technology became cheap, dissident groups and well-financed organizations used these agents to terrorize civilians in order to accomplish political goals. Examples of these attempts include the following:

- Weather Underground (1970), a US revolutionary group, intended to obtain agents from Fort Detrick by blackmail and to temporarily incapacitate US cities to demonstrate the "impotence of the federal government." Report originated with a US Customs informant.
- R.I.S.E. (1972). College students influenced by ecoterrorist ideology and 1960s drug culture planned on using agents of typhoid fever, diphtheria, dysentery, and meningitis to target the entire world population initially and later narrowed the plan to five cities near Chicago. The attack was aborted when cultures were discarded.
- Bulgarian defector Georgi Markov was assassinated in Lauda (1978) using ricin-filled pellets and a spring-loaded device disguised in an umbrella. Similar device used against a second defector in the same area was unsuccessful.
- Sverdlovsk, Russia (1979). Accidental release of anthrax from Soviet bioweapons facility caused an epidemic of inhalational anthrax with at least 77 cases and 60 deaths.
- Red Army Faction (1980). Members of a Marxist revolutionary ideology group allegedly cultivated botulinum toxin in

a Paris safe house and planned attacks against at least nine German officials and civilian leaders. This probably was an erroneous report, later repudiated by the German government.

- Rajneeshee Cult (1984). Indian religious cult headed by Rajneeshee plotted to contaminate restaurant salad bars with *Salmonella typhimurium* in Dalles, Oregon. The motive was to incapacitate voters, win local elections, and seize political control of the county. The incident resulted in a large community outbreak of salmonellosis, involving 751 patients and at least 45 hospitalizations. The plot was revealed when the cult collapsed and members turned informants.
- Minnesota Patriots Council (1991). Right-wing ''Patriot'' movement obtained ricin extracted from castor beans by mail order. They planned to deliver ricin through skin with dimethyl sulfoxide (DMSO) and aloe vera or as dry aerosol against IRS officials, US Deputy Marshals, and local law enforcement officials. The group was penetrated by Federal Bureau of Investigation (FBI) informants.
- Aum Shinrikyo (1995). New Age Doomsday cult, seeking to establish a theocratic state in Japan, attempted at least 10 times to use anthrax, botulinum toxin, Q fever agent, and Ebola virus in aerosol form. All attempts with biological weapons failed. Multiple chemical weapon attacks with Sarin, Vx, and hydrogen cyanide in Matsumato, Tokyo, and assassination campaigns were conducted. Nerve gas Sarin killed 12 and injured 5500 in Tokyo subway.
- Texas (1997). Intentional contamination of muffins and donuts with laboratory cultures of *Shigella dysenteriae* caused gastroenteritis in 45 laboratory workers and 4 were hospitalized.
- Unknown individual group (2001). Intentional dissemination of anthrax spores through the US Postal System led to the death of five people, infection of 22 others, and contamination of several government buildings. Investigation into the attacks so far has not led to any conclusions.

Although events like these do not reach the level of national or international security, they can have significant public health consequences and, therefore, require preparedness at the local level. Active surveillance and rapid response at the local level will fulfill the definition for Bioterrorism preparedness – ''think locally, act globally.''

The use of microbial agents by smaller groups or individuals who may have very limited targets is highly likely but the public health consequences are low.

- Larry Wayne Harris (1998) allegedly threatened to release ''military grade anthrax'' in Las Vegas, Nevada. He obtained plague and anthrax (vaccine strains), and repeatedly isolated several other bacteria. He then made vague threats against US federal officials on behalf of right-wing ''patriot'' groups and was arrested when he talked openly about biological weapons terrorism.

4 Bioterrorism Preparedness – The Rationale

Bioterrorism has been defined as the intentional use of a pathogen or biological product to cause harm to humans, animals, plants, or other living organisms to influence the conduct of government or to intimidate or coerce a civilian population. This definition put bioterrorism

under National Security and has prompted the recent upgrading of the Homeland Security Department in the United States. Biological agents are easy to develop as weapons, inexpensive, and difficult to detect. Biological weapons are very attractive to the terrorist because of several characteristics. Aerosols of biological agents are invisible, silent, odorless, tasteless, and are relatively easily dispersed. They are 600 – 2000 times cheaper than other weapons of mass destruction. It is estimated that the cost would be about 0.05% of the cost of conventional weapons to produce similar numbers of mass casualties per square kilometer. The production is relatively easy, using the common technology available for the production of antibiotics, vaccines, foods, and beverages. The delivery systems such as spray devices from an airplane, boat, or car are commonly available. The natural lead time provided by the organism's incubation period (3 to 7 days for most potential organisms) would allow for the terrorists' escape before any investigation starts. In addition, the use of an endemic infectious agent may cause confusion because of the inability to differentiate a biological warfare attack from a natural epidemic. For some agents, potential exists for secondary or tertiary cases by person-to-person transmission or by natural vectors. Depending on the agent, a lethal or incapacitating outcome can occur. In the military context, incapacitating agents may be more effective because the unit will not be able to perform their mission and casualties will consume scarce medical and evacuation assets.

The consequences of biological weapons use are many. They can rapidly produce mass effect that overwhelms services and the health care system of the communities. Most of the civilian population is susceptible to infections caused by these agents. They are associated with high morbidity and mortality rates. The resulting illness is usually difficult to diagnose and treat early, particularly in areas where the disease is rarely seen. One kilogram of anthrax powder has the capability to kill up to 100 000 people, depending on the mechanism of delivery. The economic impact of a biological attack has been estimated to be from 478 million/100 000 persons exposed (brucellosis scenario) to 26.2 billion/100 000 persons exposed (anthrax scenario).

5
Bioterrorism Preparedness – The Avenues

5.1
National Security and Law

Two simulated biological attacks, Dark Winter (smallpox) and TOPOFF (plague), in the United States demonstrated serious weaknesses in the public health system that could prevent an effective response to bioterrorism or severe outbreaks of naturally occurring infectious diseases. The Hanuman Redux 2001 exercise run in Louisville, Kentucky, under the auspices of the CDC, a few weeks prior to September 11, 2001, used tularemia as the biological agent. The exercise demonstrated that local, state and federal health, law enforcement, and other agencies can work together effectively. It also showed that regions with adequate bioterrorism response plans can respond to even a sizeable attack within the time frame needed to prevent mass casualties. The intentional dispersal of anthrax through the US Postal Service that followed the terrorist attacks of October 2001 brought these issues into a clear focus. The US government began

a process to strengthen the public health infrastructure.

The need for law reform was recognized as law has long been considered an important tool for the safety of the public's health. The power to act to preserve the public's health is constitutionally reserved primarily to the states as an exercise of their police powers. Some states like Colorado and Rhode Island had developed legislation or administrative public health plans for a bioterrorism event prior to September 11, 2001. The Model Act was designed to update and modernize the state public health statutes and to avoid problems of inconsistency, inadequacy, and obsolescence. The Model State Emergency Health Powers Act (MSEHPA or Model Act) was drafted by the Center for Law and the Public's Health at Georgetown and Johns Hopkins Universities at the request of the Centers for Disease Control and Prevention (CDC) and in collaboration with members of national organizations representing governors, legislators, attorneys, general and health commissioners. This act provides state actors with the powers to detect and contain bioterrorism or a naturally occurring disease outbreak. The Model Act is structured to facilitate five basic public health functions: (1) Preparedness, comprehensive planning for a public health emergency; (2) Surveillance, measures to detect and track public health emergencies; (3) Management of Property, ensuring adequate availability of vaccines, pharmaceuticals, and hospitals as well as providing power to abate hazards to the public's health; (4) Protection of Persons, powers to compel vaccination, testing, treatment, isolation, and quarantine when clearly necessary; and (5) Communication, providing clear and authoritative information to the public. The act also contains a modernized, extensive set of principles and requirements to safeguard personal rights. On the basis of MSEHPA, legislative bills have been introduced in 34 states and the District of Columbia. As of July 26, 2002, 16 states and the District of Columbia had enacted a version of the act and the states enacting or expected shortly to enact legislation, influenced by the Model Act, were Arizona, Florida, Georgia, Hawaii, Maine, Maryland, Minnesota, Missouri, New Hampshire, New Mexico, Oklahoma, South Carolina, South Dakota, Tennessee, Utah, and Virginia. A critique of the Model State Emergency Health Powers Act was published by Anna G, J., which raised concerns about the impact of the Model Act on civil liberties.

At the federal level, Public Health Security and Bioterrorism Preparedness and Response Act of 2002, HR 3448, was passed by the US Congress on May 23, 2002, and signed into law (Public Law 107–188) June 12, 2002. The bill is intended to improve the health system's ability to respond to bioterrorism, protect the nation's food supply and drinking water from bioterrorist attacks, speed up the development and production of new drug treatments and vaccines, address shortages of specific types of health professions, improve coordination of federal antibioterrorism activities, increase investment in federal, state, and local preparedness, and expand controls over the most dangerous biological agents and toxins. The American Society for Microbiology (ASM) has testified before congress on issues surrounding biosecurity and has worked closely with congress in the drafting of Title II of this law to balance public health concern over safety and security with the need to protect legitimate scientific research and diagnostic testing. Important new provisions for

the possession, use, and transfer of select agents (42 biological agents and toxins listed in Appendix A of 42 CFR part 72) are included in Title II of HR 3448, leading to enhanced Controls on Dangerous Biological Agents and Toxins. On July 12, 2002, the CDC announced preliminary guidance for notification of possession of select agents as mandated in Section 202(a) of Public Law 107–188, the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (Appendix B). The notice stated that each facility should designate a responsible facility official (RFO) to complete the notification of possession form by September 10, 2002. The RFO will need to inventory the facility and consult with others (e.g. Principal Investigators) to obtain the required information.

5.2 Medical and Scientific Preparedness

5.2.1 Assessing the Threat

A US congressional initiative to upgrade national public health capabilities for response to acts of bioterrorism was begun in 1999. The Centers for Disease Control and Prevention (CDC) was designated by the Department of Health and Human Services as the lead agency for overall public health planning. A Bioterrorism Preparedness and Response Office was formed to target several areas for initial preparedness activities including planning, improved surveillance and epidemiological capabilities, rapid diagnostic testing, enhanced communications, and medical therapeutics stockpiling. The biological agents toward which the efforts should be targeted needed to be formally identified and placed in a priority order. The strategic usefulness of multiple agents on the battlefield has formally been assessed by the military. The Working Group on Civilian Biodefense has identified several biological agents with the potential of high impact against civilian populations.

In June 1999, national public health experts, academic infectious disease experts, Department of Health and Human Services representatives, civilian and military intelligence experts, and law enforcement officials met to review the impact of various agents on civilian population. The general criteria used to assess the threat were: (1) public health impact based on illness and death, (2) delivery potential to large populations based on mass production, stability, virulence, and potential for person-to-person transmission, (3) public perception as related to public fear and potential civil disruption, and (4) special public health preparedness needs based on enhanced surveillance, diagnostic needs, and stockpile requirements. A risk-matrix analysis process was used to evaluate potential biological threat agents. On the basis of the overall ratings received in each of the four areas, the agents received final category assignments of A, B, or C (Table 1).

Category A Category A includes the highest priority agents that pose a risk to national security because of the following features:

1. They can be easily disseminated or transmitted person to person, causing secondary and tertiary cases.
2. They cause high mortality with potential for major public health impact, including the impact on health care facilities.
3. They may cause public panic and social disruption.
4. They require special action for public health preparedness.

Tab. 1 Potential agents of bioterrorism.

Category A	***Category B***	***Category C***
Variola major (smallpox) *Bacillus anthracis* (anthrax) *Yersinia pestis* (plague) *Clostridium botulinum* toxin (botulism) *Francisella tularensis* (tularemia) Filoviruses, Ebola hemorrhagic fever Marburg hemorrhagic fever Arenaviruses, Lassa (Lassa fever) Junin (Argentine hemorrhagic fever) and related viruses	*Coxiella burnetii* (Q fever) Brucella species (brucellosis) *Burkholderia mallei* (glanders) *Burkholderia pseudomallei* (Melioidosis) Alphaviruses, Venezuelan encephalomyelitis Eastern and Western equine\Encephalomyelitis Ricin toxin from *Ricinus communis* (castor beans) Epsilon toxin of *Clostridium perfringens* Staphylococcal enterotoxin B T2 – Mycotoxins Food or waterborne pathogens include but not limited to Salmonella species *Shigella dysenteriae* *Escherichia coli* 0157.H7 *Vibrio cholerae*, and *Cryptosporidium parvum Rickettsia prowazekii* (*Typhus* fever) *Chlamydia psittaci* (Psittacosis)	Nipah virus Hantaviruses Tick-borne hemorrhagic fever viruses Tick-borne encephalitis viruses Yellow fever Multidrug-resistant tuberculosis

Category B This category contains the second highest priority agents because they

1. are moderately easy to disseminate;
2. cause moderate morbidity and low mortality;
3. require specific enhancement of CDC's diagnostic capacity and enhanced disease surveillance.

Category C The agents in this group with the third highest priority include emerging pathogens that could be engineered for mass dissemination. The characteristics that render them amenable to bioterrorism are:

1. Availability
2. Ease of production and dissemination
3. Potential for high morbidity and major health impact.

5.2.2 Training and Recognition

To diagnose the illnesses caused by potential bioterrorism agents, the health care professionals must be aware of the symptoms and epidemiology patterns that may indicate a covert or unannounced attack.

A terrorist attack may occur in two scenarios – overt and covert. In the past, emergency responses were prepared on the basis of overt attacks like bombings and chemical agents that cause immediate and obvious effects. However, attacks with biological agents are more likely to be covert. They pose different challenges and require emergency planning, with the involvement of the public health

infrastructure. The attack by a biological agent will not have an immediate impact because of the delay between exposure and onset of illness (i.e. the incubation period). Therefore, the first victims of a bioterrorism action will need to be identified by physicians or other primary health care providers. On the basis of the first wave of victims, public health officials will need to determine that an attack has occurred, identify the organism, and prevent more casualties through prevention strategies (e.g. mass vaccination, prophylactic treatment) and infection-control procedures. The clues to a potential bioterrorist attack include an outbreak of a rare or new disease, an outbreak of diseases in a nonendemic area, a seasonal disease during an off-season time, a known pathogen with unusual resistance or unusual epidemiologic features, an unusual clinical presentation or age distribution, a genetically identical pathogen emerging rapidly in different geographical areas, reports of sick or dead animals or plants, and intelligence information.

It is now recognized that emergency departments (EDs) are critical partners in the early recognition of emerging public health threats. Early recognition depends on epidemiologic warning networks from the local and national public health agencies and the clinical knowledge and increased index of suspicion by the health care providers working in emergency departments and urgent care centers. The ED Surveillance System, known as *EMERGEncyIDNET*, designed to detect emerging infectious diseases, started as a collaboration between 11 academic EDs and the CDC. Food Net, the Foodborne Disease Active Surveillance Network is an analogous program also coordinated by the CDC and is designed to monitor and track foodborne diseases.

Although very useful, such large databases may not be able to provide timely response without vigilance of local health care providers. Surveillance systems based in ambulatory care settings provide worthwhile additional information in a more timely fashion. The Department of Defense Electronic Surveillance System for the Early Notification of Community-based Epidemics (ESSENCE) is one of the best known such systems. Minnesota operates another such system. A system of automated ambulatory care encounter records for the detection of acute illness clusters has been developed between the Centers for Disease Control and Prevention and the Massachusetts Department of Public Health, a large group practice, a health plan, and an academic department. The system is designed to produce next-day information about illness clusters, based on ambulatory care visits and telephone calls. Such measures to strengthen the surveillance systems and improved training of health care providers will be critical to effective planning and readiness. A task force of health care professionals, central to detecting and responding to a bioterrorism incident, was convened by the American College of Emergency Physicians. The goal is to examine educational strategies, curricula, teaching methods, and certification processes with the outcome of better-prepared ''frontline'' health care professionals.

5.2.3 Disease Reporting – A Tool for Determining Bioterrorism Preparedness

The timely and accurate reporting of the diseases caused by biological agents would likely be the triggering event for investigating and responding to a bioterrorism

event. The quality and distribution of laws mandating the reporting of disease caused by certain biological agents is one measurement of the public health system's level of bioterrorism preparedness. The CDC's Bioterrorism Preparedness and Response Program commissioned a study of state and local laws requiring the reporting of diseases caused by specific biological agents. These agents are regarded as ''critical biological agents'' because of their potential to harm the public health, especially if used in a terrorist act. As of March 31, 2001, this commission reported a significant variability in disease-reporting requirements pertaining to critical biological agents in the 50 states, the District of Columbia, Chicago, New York, and Los Angeles County. Some jurisdictions may have revised these requirements since September 2001. The commission's findings suggest the draft Model State Emergency Health Powers Act as a useful template for states considering revisions to reporting laws. The Model State Act addresses which diseases should be reported, who should be legally obligated to report, the manner and time frame in which a disease should be reported, and the enforcement of disease-reporting laws. Such laws may also serve as educational tools and provide incentives for health care providers to obtain the necessary training and skills for diagnosing and managing potential agents of bioterrorism.

5.2.4 Planning and Readiness – Public Health Preparedness

The National Association of Counties recently conducted a survey of the Directors of County Public Health Departments, which represented 300 counties in 36 states. A significant number of responding counties reported less than optimal levels of preparedness for biological threats and for policies and procedures to enforce quarantine. Among the reasons cited for lack of preparedness were insufficient funding, work force, and communication networks. In most cities in the United States, large health care institutions have disaster plans and various types of task forces with ''experts'' in different areas in place. However, they need to be updated and modified to include new information on potential agents of bioterrorism. The CDC was designated by the Department of Health and Human Services to prepare the US Public Health System to respond to bioterrorism events. A strategic plan was developed by the CDC in collaboration with the National Center for Infectious Diseases, the National Center for Environmental Health, the Public Health Practice Program Office, the Epidemiology Program Office, the National Institute for Occupational Safety and Health, the Office of Health and Safety, the National Immunization Program, and the National Center for Injury Prevention and Control. In order to enhance the preparedness at local and state levels, the CDC funded cooperative agreements with states and several large cities. During the first three years of the program (1999–2001), five areas were emphasized: (1) Preparedness, planning, and readiness assessment; (2) surveillance and epidemiology capacity; (3) biological laboratory capacity; (4) chemical laboratory capacity and; (5) health alert network and training.

Recognizing the pivotal role of rapid laboratory identification of bioterrorism agents and the limited laboratory experience with Category A agents in the United States, the Laboratory Response Network (LRN) for Bioterrorism was established.

The CDC and the Association of Public Health Laboratories developed LRN for bioterrorism in collaboration with the Federal Bureau of Investigation (FBI), United States Army Medical Research Institute of Infectious Diseases, the Naval Medical Research Center, and Lawrence Livermore National Laboratory. The LRN became operational in August 1999, and is a multilevel system that links state and some local public health laboratories with military, veterinary, agricultural, water, and food-testing laboratories. The network of laboratories is designated Levels A through D with progressively stringent levels of safety, containment, and technical proficiency needed to perform the essential rule-out, rule-in, and referral functions required for identification of agents. Level A laboratories are the hospital and other clinical laboratories that participate in the LRN by ruling out or referring the critical agents to the nearest Level B or C laboratory. Levels B, C, and D laboratories have access to the biodetection assays and specialized agents that are used in protocols for the confirmation of critical agents. Level B laboratories are state and local public health laboratories with Biosafety Level 2, where Biosafety Level 3 practices are observed. Level C laboratories are Public Health laboratories with Biosafety Level 3 facilities or certified animal facilities for performing the mouse toxicity assay for botulinum toxin. They perform all Level B tests and additional tests requiring Biosafety Level 3 containment, including the handling of powders suspected of containing anthrax spores. Level D laboratories are the federal laboratories at the CDC and the United States Army Medical Research Institute of Infectious diseases. They have Biosafety Level 4 capacity to handle agents like smallpox and Ebola.

5.2.5 Decontamination and Infection-control Procedures

The information in this section refers to procedures used by health care institutions if and when patients with communicable diseases including those caused by the agents of bioterrorism are managed.

The Association of Professionals in Infection Control and Epidemiology (APIC) in cooperation with the CDC has prepared a Bioterrorism Readiness plan to serve as a reference document and a template to facilitate preparation of bioterrorism readiness plans for individual institutions.

Decontamination methods have an important role in the control of infectious diseases. However, the procedures have to be safe for people and materials they are used on. Examples of mechanical decontamination are water filtration, air filtration, and washing with water. Skin surfaces can be easily decontaminated by careful washing with soap and water. Chemical decontamination (disinfectants) used in the form of liquid, gas, or aerosol render biological agents harmless. Some of these are harmful to humans, animals, and the environment. Grossly contaminated skin surfaces should be washed with 0.5% sodium hypochlorite solution with a contact time of 10–15 min. Physical agents (head, radiation) are employed for decontamination of objects. The potential agents of bioterrorism that can be transmitted person to person require patient-isolation precautions. In addition to standard precautions employed in the care of all patients, airborne precautions, droplet precautions, and contact precautions are recommended for patients with smallpox, pneumonic plague, and viral hemorrhagic fevers respectively.

The personal protective equipment currently in use in the health care facilities in the United States is adequate for dealing with infectious agents with various modes of transmission. The USAMRIID maintains an aeromedical isolation team to minimize the risk of transmission from the troops to the aircrew, caregivers, and civilians.

Patient-isolation precautions – Appendix B: USAMRIID's medical management of biological casualties handbook

Standard Precautions

- Wash hands after patient contact.
- Wear gloves when touching blood, body fluids, secretions, excretions, and contaminated items.
- Wear a mask and eye protection, or a face shield during procedures likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.
- Handle used patient-care equipment and linen in a manner that prevents the transfer of microorganisms to people or equipment.

Use care when handling sharps and use a mouthpiece or other ventilation device as an alternative to mouth-to-mouth resuscitation when practical.

Standard precautions are employed in the care of ALL patients.

Airborne precautions

Standard Precautions Plus

- Place the patients in a private room that has monitored negative air pressure, a minimum of six air changes/hour, and appropriate filtration of air before it is discharged from the room.
- Wear respiratory protection when entering the room.
- Limit movement and transport of the patients. Place a mask on the patients if they need to be moved.

Conventional diseases requiring airborne precautions: measles, varicella, pulmonary tuberculosis.

Biothreat diseases requiring airborne precautions: smallpox

Droplet precautions

Standard Precautions Plus

- Place the patients in a private room or cohort them with someone with the same infections. If not feasible, maintain at least 3 ft between patients.
- Wear a mask when working within 3 ft of the patients.
- Limit movement and transport of the patients. Place a mask on the patients if they need to be moved.

Conventional diseases requiring droplet precautions: Invasive *Haemophilus influenzae* and meningococcal disease, drug-resistant Pneumococcal disease, diphtheria, pertussis, mycoplasma, GABHS, influenza, mumps, rubella, parvovirus.

Biothreat diseases requiring droplet precautions: pneumonic plague.

Contact precautions

Standard Precautions Plus

- Place the patients in a private room or cohort them with someone with the same infection if possible.
- Wear gloves when entering the room. Change gloves after contact with infective material.
- Wear a gown when entering the room if contact with patient is anticipated or if the patient has diarrhea, a colostomy, or wound drainage not covered by a dressing.

- Limit the movement or transport of the patient from the room.
- Ensure that patient-care items, bedside equipment, and frequently touched surfaces receive daily cleaning.
- Dedicate use of noncritical patient-care equipment (such as stethoscopes) to a single patient, or cohort of patients with the same pathogen. If not feasible, adequate disinfection between patients is necessary.

Conventional diseases requiring contact precautions: MRSA, VRE, *Clostridium difficile*, RSV, parainfluenza, enteroviruses, enteric infections in the incontinent host, skin infections (SSSS, HSV, impetigo, lice, scabies), hemorrhagic conjunctivitis.

Biothreat diseases requiring contact precautions: viral hemorrhagic fevers.

5.2.6 Pharmaceutical Readiness

The United States Food and Drug Administration (FDA) is participating in an interagency group for response in a civilian emergency. The group represents the Department of Defense, the Veteran's Administration, CDC, NIH, and the Office of Emergency Preparedness. The regulation of medical products by the FDA is based on science, law, and public health considerations. Research conducted at the FDA's Center for Biologics Evaluation and Research contributes to the defense against bioterrorism agents. These efforts include design of new vaccines, pathogenesis and mechanism of replication of bioterrorism agents, new methods and standards to expedite the review of new vaccines and immunoglobulins. The FDA also proposes standards for the use of animal efficacy data in approving new products and ensures appropriate product surveillance and compliance.

Stockpiling of supplies, antimicrobial agents, and vaccines is considered the key mechanism for rapid response to a bioterrorism threat and/or event. Stockpiles have been created by the Department of Health and Human Services that can reach any community within 12 h. Special teams will accompany the stockpiles to aid in unpacking and preparing for distribution. The use of stockpiled antibiotics for mass protection has the disadvantages of side effects, intolerances, and lack of efficacy against genetically engineered bioterrorism agents. In addition to the use of antimicrobial agents for postexposure prophylaxis, administration of passive antibody has been proposed as a biological defense initiative. Specific antibodies are active against the major agents of bioterrorism, have low toxicity, and provide immediate protection. Various models and estimates of the economic impact of bioterrorism attacks have been published. Rapid implementation of a postattack prophylaxis program is the single most important means of reducing the huge economic impact. The model proposed by Kaufamnn et al. provides economic justification for preparedness measures. Unlike the military, there are not enough emergency providers who have received sufficient immunizations to care for patients with infections due to critical biological agents. Efforts to immunize health care providers against smallpox and create a ''smallpox response team'' in most areas of the country have been started in the United States. After immunizing about 40 000 personnel, the process is currently suspended. However, smallpox vaccination can be protective even when given 3–4 days after infection. Thus, the personnel needed to manage patients will be able to be protected from the time smallpox is diagnosed. The currently available anthrax

vaccine is being given to all deployed military personnel. More efficacious anthrax vaccines with fewer injections are under study.

5.3 Political Preparedness

The single most important issue in any preparedness plan is to know who will be ''in charge.'' This question must be adequately answered before an emergency arises. All local hospitals and governments should have an action plan, with responsible personnel and their alternates in place prior to the incident.

Following the Oklahoma City bombing, President Clinton signed Presidential Decision Directive 39 (PDD-39), which places the management of such attacks under the Federal Bureau of Investigation (FBI) and the Federal Emergency Management Agency (FEMA) for domestic incidents. The preparations include site surveys, assessment of local resources to treat victims, and status of local stocks of antidotes. The US Congress followed this with Public Law 104–201, the Defense against Weapons of Mass Destruction Act.

The Office of Homeland Security, created in the aftermath of the September 11, 2001, attacks, was upgraded to a full Department of the Federal Government in June 2002 by President George W. Bush. The Department is likely to have a budget of $32 billion a year, including several hundred million for research. The biodefense research will yield results applicable to natural infectious diseases also. However, the advantages of disseminating the results to researchers can be offset by the information also reaching the terrorists.

The Department of Defense has the greatest capability in Biodefense for the military forces. In the civilian context, the responsibility for dealing with the effects of biological agents falls into multiple venues, including many federal, state, and local governments, and ultimately the civilian medical community. The Department of Health and Human Services has the lead role and the bulk of the resources.

5.4 Global Preparedness Against the Threat of Bioterrorism

As in the case of outbreaks of natural infectious diseases, diseases caused by potential agents of bioterrorism have quick and devastating global implications. Most countries do not have the resources to prepare against bioterrorism attacks or the spread of bioterrorism agents. The World Health Organization (WHO) with over 50 years of experience has the task of a rapid, multifaceted response needed to contain outbreaks quickly and prevent their international spread. The staff, consultants, and expert advisors of WHO have privileged access to all countries. WHO's permanently positioned geographical resources include the Geneva headquarters, six regional offices, and 141 country offices located in close proximity to ministries of health. The country offices are concentrated in the areas where epidemics are most frequent and new diseases are most likely to emerge. All offices are linked electronically to WHO and its global network of institutional resources and collaborators. The network of formally designated WHO collaborating centers consists of 250 laboratories and institutions. In addition, many laboratories and public health institutions collaborate with WHO on a regular basis. WHO has a very close

working relationship with CDC, including direct secondment of staff. It also uses technical support from laboratories included in the US Department of Defense Global Emerging Infections Surveillance and Response System (DOD – GEIS) and similar laboratories in other WHO member states. Other US agencies that provide technical and financial assistance for WHO sponsored programs are US-AMRIID, NASA-Goddard Space Flight Center, the National Centers for Environmental prediction, the National Institutes of Health, and the US State Department's Bureau of Population, Refugees, and Migration.

WHO is politically neutral and greatly needed in the developing world. Ministries of Health in these countries rely upon WHO as the single most important source of authoritative advice and technical assistance pertaining to the control of infectious diseases. The epidemiological techniques needed to investigate natural and deliberate outbreaks are the same. WHO coordinates a large number of electronic ''detective'' systems and databases to keep watch over known risks as well as unexpected or unusual disease events. FluNet, established more than 50 years ago, is the oldest of these and has served as the prototype for the design and implementation of many other systems. The recent establishment of innovative mechanisms for detection and response to unknown diseases or unusual or unexpected disease events has added to the global preparedness against bioterrorism. WHO scans the world through a semi-automatic electronic system developed by Health Canada that continuously and systemically crawls websites, news wires, public health e-mail services, electronic discussion groups (e.g. US-based ProMED), and local on-line newspapers for definitive and rumor-based information. The World Health Assembly, the supreme governing body of WHO, adopted a consensus resolution on global health security in May 2001. This allows the WHO to investigate and verify rumored outbreaks even prior to receipt of an official notification from the government of the country concerned. To combine heightened vigilance with a rapid response, WHO has formed the Global Outbreak Alert and Response Network and issued guidelines for the behavior of foreign nationals during and after field operations in the host country.

Strengthening and building national epidemic detection and response is far more cost effective than mobilizing an international response. In order to improve preparedness in different parts of the world, WHO has formed the Training Programs in Epidemiology and Public health Interventions Network and established a working group on long-term preparedness for outbreak response. Through these programs, Early Warning and Response Networks have been started in partnership with nongovernmental organizations present in the field. Efforts at systematic capacity building among the local communities help sustain the effects of international assistance. Sustained improvements in civil administration through the establishment of a community registry of births and deaths is the most significant step in the path to detection and global preparedness against infectious diseases threats including those related to bioterrorism and will allow the medical community to ''think locally and act globally.'' WHO has issued an updated edition of its standard guide to health aspects of chemical and biological weapons.

Like the national efforts, international efforts of protecting global health are governed by laws. International Health Regulations (IHR) adopted in 1951 provided the only legally binding instrument implemented by WHO, governing the reporting of epidemic-prone diseases and the application of measures to prevent their spread. The IHR's contribution to international governance on infectious diseases was questioned in the late nineteenth century (called *International Sanitary Conventions*, then) and its problems analyzed in the 1960s and 1970s. WHO launched efforts to revise the IHR for new globalization challenges. Currently, the global Network operates without the revised IHR in place. The strengthening of global surveillance under the revised IHR centers on requiring member states to report all ''public health emergencies of international concern'' to WHO. The definition of public health emergency would be based on WHO-developed criteria, including whether or not the event is serious, unexpected, and likely to involve the international spread and to trigger trade and travel restrictions. WHO has also proposed that the member states make confidential, provisional notifications and have national surveillance systems that meet minimum requirements.

The second objective of IHR is to provide maximum protection against international disease spread with minimum interference with world traffic. In the recent WHO proposals, changes are mentioned as ''recommendations.'' WHO already possesses the power to issue recommendations (WHO Constitution, Article 23). Before any rule becomes binding, World Health Assembly approval is required (WHO Constitution, Article 21). Owing to the guarding of sovereignty by member states and the required approval by the World Health Assembly, the revised IHR would allow WHO to only make recommendations. The revised IHR does not address what happens when member states ignore WHO recommendations. The role of international law in the control of infectious disease is more important today than it has ever been but remains uncertain.

Keywords

BAC
Bacterial artificial chromosome.

cDNA
Complementary DNA, DNA that corresponds to all or part of a gene transcript.

DNA Microarray
Sometimes also called a *"gene chip,"* spots of DNA are placed in a two-dimensional array on a surface, typically either a glass surface or a nylon surface, so that a nucleotide sequence labeled for detection may be hybridized to the DNA on the surface and quantified.

Embryo
After fertilization of an ovum, the resultant zygote and subsequent stages until birth are collectively considered ''embryonic.'' In human and other larger animals, the later stage embryo is called a fetus.

Genome
The entire nucleotide sequence of an organism's chromosomes.

Genomics
Field of study that addresses biological questions at the scale of the genome or transcriptome.

Hybridization
The process of annealing complementary nucleotide sequences, as performed in a variety of techniques, including DNA Microarrays, SAGE, ISH, and RT-PCR.

ISH
In situ hybridization, a technique used to characterize the localization of mRNA in cells and tissues by visualizing (using microscopy) labeled probes that hybridize with RNA in the cell.

PCR
Polymerase Chain Reaction, a method using known probes flanking a nucleotide sequence of interest and cycles of polymerase action to amplify, or make many copies of, that sequence of interest.

RT-PCR
Real Time PCR (RT-PCR), a variation of PCR that scales the amplified nucleotide sequence of interest to the original frequency of that sequence, thereby allowing an accurate measure of the original abundance.

SAGE
Serial Analysis of Gene Expression, a technique that estimates the amount of mRNA expression by ligating small pieces, or tags, of the entire set of expressed transcripts, determining the sequence of this ligated sequence, and counting the occurrence of each tag.

Transcriptome
The collection of sequences and abundances of all transcripts, or RNAs, uniquely collected from a cell type, tissue, organ, or whole organism.

Embryogenomics, or developmental genomics, is defined as a systematic analysis of embryo development with large-scale approaches. This systematic analysis permits consideration of the system as a whole by keeping whole genome sequences and a complete gene catalog in perspective. By merging genomics and developmental biology, embryogenomics contributes to both disciplines: large-scale methodologies and genomewide concepts are contributed to developmental biology and the materials and knowledge of genes specifically expressed in embryos are contributed to genomics. Here, we review the history and recent strides in this effort, including discussions of the genome projects, cDNA library construction, and large-scale experiments and analysis for model organisms that have the greatest impact on the field of embryology. We will emphasize progress in mouse embryogenomics as it provides the basis of discussion for what is arguably the most accessible model organism with a developmental plan that has high similarity to that of humans. Finally, the status of current technologies as they relate to embryogenomics, the obstacles to overcome, and the future aims for this new field are discussed.

1 Introduction

One of the fundamental questions in developmental biology is how the expression of individual genes is regulated in specific cell types and how the differential expression/action of genes drive the development of complex organisms from a simple form (e.g., fertilized eggs in animals). In the 1960s and early 1970s, hybridization kinetic analyses of early embryos and many different cell types was used to examine global transcriptomes and this established that different groups of genes are indeed actively transcribed in each cell type. The majority of these RNA molecules, however, could not be identified at that time. The advent of molecular cloning in mid-1970s made it possible to isolate and characterize individual genes that play crucial roles in the development of organisms. This one-gene-at-a-time approach has become the standard of molecular developmental biology and forms the foundation of our current understanding of development. Using such an approach, however, it is difficult to provide a global view of genome-wide gene actions. Simultaneous expression analyses of hundreds of genes during development began in the early 1980s with hybridization measurements from cDNA clones spotted on membranes. The extension of such analyses to entire genomes began to be formulated in the early 1990s. The earlier approaches can satisfy both global aspects of gene expression as in 1960s to 1970s and individual gene aspects of gene expression since the 1970s, but owing to the much larger scale of whole transcriptome/genome studies, the development of new technologies was inevitable. The Human Genome Project that began in late 1980s revolutionized molecular biology by developing and incorporating large-scale technologies into biology. Massive handling and analysis of DNA clones, aided by robotics and informatics, are for the first time brought into biology. As such, embryogenomics emerges at the interface between genomics and developmental biology.

Genomics offers three main conceptual frameworks to developmental biology. First, large-scale approaches offer investigators the ability to screen a large number of candidate molecules simultaneously to determine which candidates are of interest for further study of the phenomenon of interest. Large-scale efforts in molecular biology offer a cost-effective method of providing comprehensive resources and data sets. The development of permanent, reusable resources (e.g. cDNA clone archives), once and for all establish a strong infrastructure, thus increasing the efficiency of development research. These reusable resources for large-scale approaches offer a huge advantage and increase in the pace of research over previous techniques that allowed only a very limited subset of molecules to be screened in a single experiment. This advantage also brings the paradoxical problem of having more data available from one experiment than one would previously obtain from hundreds or even thousands of experiments prior to the advent of technologies such as DNA microarrays. With this tidal wave of data comes the necessity of improving analytical and data-visualization techniques so that the results can be fully analyzed and understood.

Second, while the cost-effectiveness of comprehensive coverage provides a central motivation for large-scale efforts, an ongoing pursuit in the use of large-scale approaches in molecular biology is motivated in part by the desire to move

from using large-scale endeavors as merely screening tools (data) to synthesizing the results with the results of other techniques to build sophisticated models (knowledge). Embryogenomics poses questions at a large scale compared to how questions are framed with traditional molecular biology techniques. Integrative approaches to large-scale questions have the best hope of providing cohesive answers. While questions that aim at a larger scale have the merits of efficiency and broadened perspective, the real advantage of embryogenomics is the ability to begin considering the combinatorial actions of molecules in the specification of developmental processes. This interface of embryogenomics with systems biology approaches allows a reevaluation of the one-gene-at-a-time paradigm to development research.

Third, the evolutionary aspects of developmental biology will be explored through comparative genomics. The completion or draft completion of many projects to sequence entire genomes has ushered in the so-called postgenomic era for molecular biology. The National Center for Biotechnology Information (NCBI) currently reports some genomic sequence entries for 59 metazoan species (Fig. 1). Comparisons of the genome sequences of different species provides opportunities to identify orthologous genes and conserved regulatory sequences. The emerging view is that molecular mechanisms executed by orthologous genes operate similarly in different species.

Genomics approaches also benefit from the interface with embryogenomics because of the experimental knowledge and materials offered by embryogenomics approaches. While available genome sequences play a central role in large-scale approaches (Fig. 2), much of our understanding of transcript expression and gene structure within the genome comes from cDNA collections, where transcripts or partial transcripts may be assembled into consensuses and mapped to the genome. Construction of these cDNA libraries is normally performed with adult tissues because these tissues are easier to obtain. Consequently, cDNAs uniquely expressed in embryonic tissues will not be represented in these libraries, and inference of gene structure from transcripts could not be achieved for these embryo-specific sequences. Efforts to build libraries from embryonic tissues have contributed to the ability of genomics approaches to identify gene structures, both for the genes actually represented by these libraries and for others through computational predictions using these unique transcripts as part of their training set.

Our definition of embryogenomics is somewhat broad, and so we will focus our discussion primarily on organisms and large-scale approaches that are most aptly suited for investigation of development at the level of the transcriptome.

2 Approaches

2.1 Complementary DNA (cDNA) Projects

Expressed sequence tags (ESTs) are short sequence reads from either the 5′ or 3′ end of complementary DNA (cDNA). Construction of cDNA libraries and large-scale analysis of these libraries forms part of the core of embryogenomics. Building a gene catalog from the fundamental gene identification and gene structure information provided by EST projects is a prerequisite for most of the expression profiling techniques we discuss below (Sects 2.2 and

Fig. 1 Taxonomy of the 59 metazoan species with genome entries in NCBI's database. These species are listed as those for which NCBI holds submitted genomic sequences. Adapted from the NCBI Web site: http://www.ncbi.nlm.nih.gov/PMGifs/genomes/new_euk.html.

2.3). ESTs give gene signatures, which help define gene structure by alignment with the genome, and they allow for an evaluation of the frequency of randomly selected cDNA clones within a library. The cDNA clones from which ESTs are derived are useful for functional studies of a particular gene or may be used as part of a collection in large-scale efforts such as spotting on cDNA microarrays or in large-scale *in situ* hybridization.

Early efforts at cDNA library construction and EST sequencing typically resulted in clones with relatively short inserts

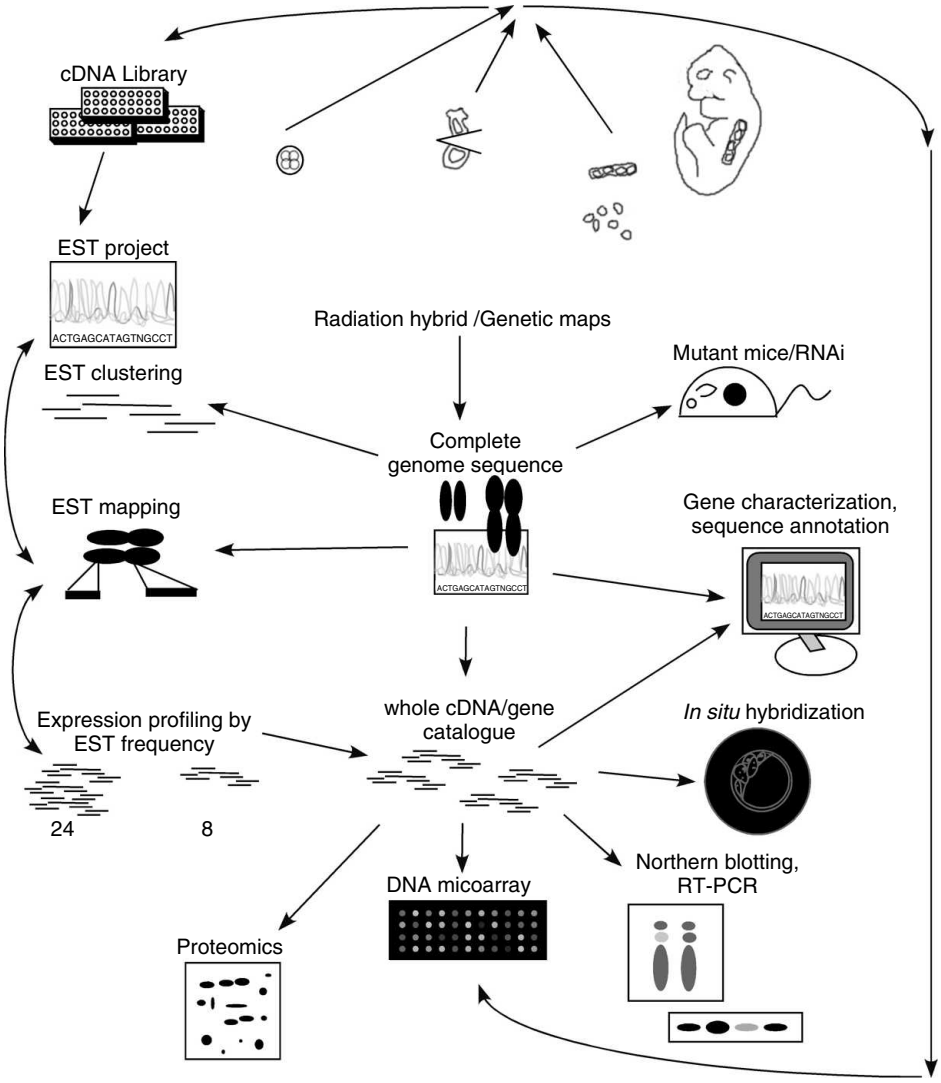

Fig. 2 Available genome sequences play a central role in embryogenomics and other large-scale biology.

(~1.5 kb average insert size) with relatively short EST sequence reads (100–500 bp). These truncated sequences are useful as unique tags for functional studies and for defining gene boundaries. Demand for more complete sequences and gene definitions have driven development of technologies to increase clone insert length and sequence read length, and there is high interest in collecting cDNA clones with full-length inserts.

While several cDNA projects began in the early 1990s, most of these early efforts constructed libraries from adult tissues, resulting in the assembly of gene indices mainly representing adult organisms. As

expression of some genes is likely to be specific to certain developmental stages or tissues, this practice of constructing cDNA libraries from adult tissues results in the exclusion of uniquely expressed developmental genes from gene indices.

2.2 Large-scale Analysis of Gene Expression at the Transcriptome Level

Profiling the expression of genes at a large scale gives valuable insights into which genes are important to, or have unique expression patterns in, a particular cell type, or which genes have enriched or depleted expression in response to a given cue.

Several issues, all concerning the complexity of biochemical and gene regulatory networks *in vivo* and *in vitro*, confound our efforts to analyze expression data and reconstruct gene regulatory networks from that analysis: (1) transcript expression and protein activity sometimes do not correlate; (2) although we readily gather information about how a single gene varies expression between samples, finding absolute expression values so the expression levels of different genes may be compared is not yet a standard practice; (3) comparisons of different cell types may lead to erroneous conclusions because of heterogeneity of some sample collections and volumetric differences between cell types; and (4) even when the experimental conditions are well described (see MIAME compliance, below), it is not yet clear how the results from different experimental platforms and methods may be compared.

Genomics approaches, such as the use of microarrays, force questions or hypotheses to be framed at a different scale or purpose. While genomics approaches may not always give consistent answers or provide biological "truth," the same is true for traditional biological methods, which have certainly provided some mistaken conclusions. Just as integrative approaches are used to independently verify traditional experiments, the same is necessary for microarrays and other high-throughput approaches, and this should not be of any surprise. Conversely, these high-throughput approaches are also not a panacea for biological discovery but instead a useful tool to ask very broad questions that cannot be otherwise asked.

We will first discuss some of the primary techniques used to determine expression profiles without spatial resolution, and then end this section with a discussion of recent efforts at large-scale *in situ* hybridization. In situ hybridization (ISH) offers spatial resolution of transcripts, but most approaches have poor quantitative resolution. ISH thus complements quantitative techniques of expression profiling.

2.2.1 EST Frequency

Standard (not normalized or subtracted) EST libraries are thought to be random samplings of the transcriptome from the cell type or tissue it was derived from. As such, it has been proposed by Meyerowitz that EST frequencies correlate with the relative abundance of each transcript in the sample. EST sequences are obtained from cDNA libraries, which are transcript-encoding sequences or sequence fragments that have been cloned into plasmids and then cultured in a biological host (Fig. 3(a)). The primary consideration for the construction of cDNA libraries is to identify and analyze gene structures, to make these cDNA clone sequences available for spotting on cDNA microarrays, or to make these clones available for downstream functional studies. Availability of EST sequences for the analysis of

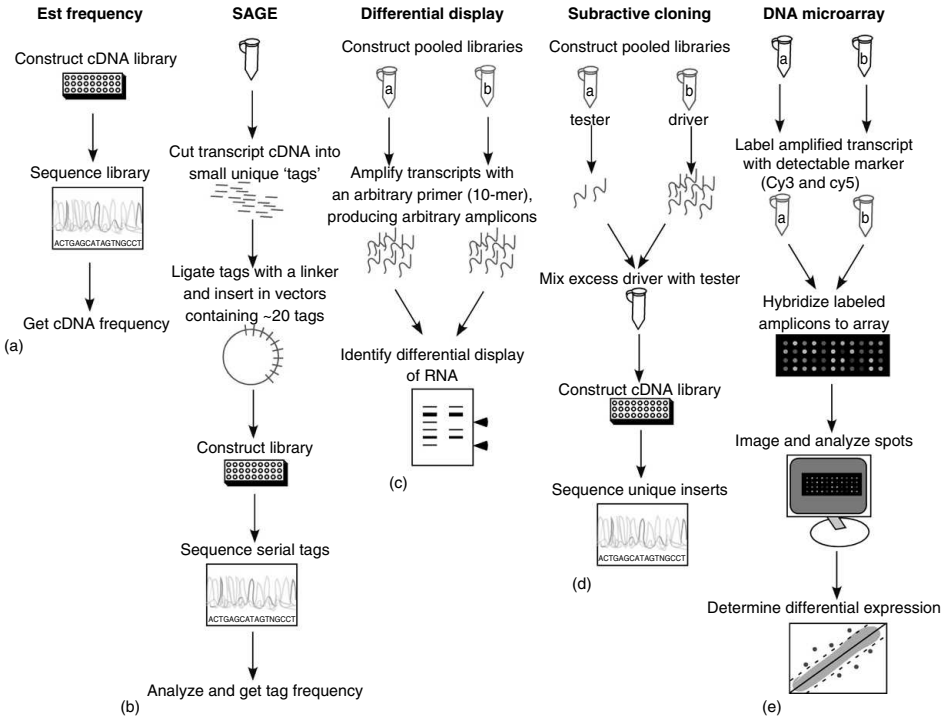

Fig. 3 Techniques for measuring differential expression.

EST frequencies is an additional benefit of cDNA projects, which have the primary goal of providing sequenced cDNA clones as reagents for molecular biology investigations.

2.2.2 SAGE

Serial Analysis of Gene Expression (SAGE) offers an alternate strategy for quantifying gene expression. SAGE is essentially an accelerated version of determining EST frequency from an EST sequencing project. Expressed sequences are cut with restriction enzymes to produce small unique "tags" representing each expressed sequence. These tags are ligated together with linker sequences into vectors containing approximately 20 tags separated by the linker sequences. Sequencing of these vectors allows frequency of the expressed sequences to be determined in a high-throughput capacity, when compared to normal EST sequencing efforts (Fig. 3b). Many plasmid clones must be sequenced for SAGE, but these costly sequencing efforts produce only the expression profiles without producing the reagents to be used for other purposes as in EST projects.

2.2.3 Subtractive Cloning

One strategy for cloning transcripts that are uniquely expressed in one of a pair of transcriptomes is to use subtractive cloning, which removes transcripts common to the pair. An investigator chooses the transcriptome in which they are looking for novel transcripts, called the *tester*, and chooses which transcriptome will be

used to subtract nonunique clones, called the *driver*. Using modern PCR methods, double-stranded cDNA from the cells or tissues of interest is created, linkers are ligated to the ends of the cDNA, and the cDNA pools are amplified using PCR. After amplification, the linkers are removed and unique linkers are ligated to the tester pool. The tester pool is then hybridized to a large excess of the driver. Tester–tester hybrids (cDNA unique to the tester pool) are then amplified using PCR (Fig. 3c). The so-called representational difference analysis (RDA) of cDNA makes use of two rounds of hybridization, because tester–tester hybrids in the first phase of hybridization may arise because of random annealing events and thus may not necessarily be unique to the tester pool.

2.2.4 Differential Display

Another PCR technique used to find unique transcripts is differential display, or RNA fingerprinting, which amplifies the transcriptome by first using reverse transcriptase and oligo-dT primer (or another arbitrary primer) to make cDNA from the transcriptome; then, arbitrary transcript fragments are amplified using poly-dT primer and another arbitrary primer (usually a 10-mer). Differences in transcriptomes are evaluated by electrophoresis of the two amplified pools (Fig. 3d).

2.2.5 DNA Microarrays

DNA microarray technology has been leading the way in offering applications and knowledge-seeking strategies in large-scale biology. Microarrays give a snapshot of gene expression for thousands of transcripts simultaneously.

Three types of microarrays are currently used: (1) cDNAs spotted on either glass slide or nylon membranes; (2) 25-mer oligonucleotides synthesized by the lithographic technique (Affymetrix); (3) 50- to 80-mer oligonucleotides synthesized *in situ* (e.g. Agilent) or spotted on either glass slide or nylon membrane. Transcripts are labeled, typically with Cy3 and Cy5 flourophores for two-channel glass arrays, and with the radioisotope phosphorous-32 for one-channel nylon membranes. When transcripts are collected from rare sample tissues such as preimplantation embryos, they are often linear-amplified by *in vitro* RNA polymerase reaction and then hybridized to the microarray. The intensity of the spot is used as a means of quantifying the transcript abundance relative to the abundance of the same transcript from a different sample, which may be measured in the second channel on the same two-channel array, or measured from a different array when using one-channel arrays (Fig. 3e).

While DNA microarrays are the best large-scale expression profiling method at this point and offer many insights previously inaccessible by traditional experiments, there are still problems facing those who would use microarrays in their investigations, including questions of how to design experiments, how to analyze the data, and the biggest problem: how to achieve reproducibility between different experiments and investigators.

2.2.6 Experimental Design

For the present, the most important aspect of array experiments is proper experimental design. The analysis of microarray data is a subject of discussion and controversy, but several currently popular techniques of analysis will be effective if experiments are properly designed. Some difficulties may arise in choosing a design strategy because no one design is suitable for all types of experiments or for all

practical considerations, such as the availability of resources. Some of the design problems one is faced with include: the biological questions being asked (or which comparisons are the most important to consider), whether to use a universal reference sample, the number of hybridizations that can be performed, sample availability, technical variability, biological variability, and the desired compatibility with future experiments.

2.2.7 **Reproducibility**

Although many laboratories have produced quality microarray experiments with acceptable reproducibility, the reproducibility of experiments and conclusions between different labs remains a strong challenge to the scientific community. Even when researchers experiment to answer the same questions with microarrays of the same construction, the results and conclusions may be very different. The formulation of guidelines for data sharing in the Minimal Information About a Microarray Experiment (MIAME) standard has been an important step toward realizing the goal of reproducibility. Here ''Minimal'' is something of a misnomer, as the MIAME standard requires reporting all aspects of the microarray experiment, including detailed information about the platform, sample collection, and all hybridizations.

Standardization of microarray data analysis will also be of benefit to the scientific community by promoting a common understanding of techniques used and by allowing for greater ease of comparing results from different groups. This will come with time as the best techniques emerge from the numerous available ideas. The use of the False Discovery Rate (FDR) is one example of recent progress toward an improved standard of microarray analysis. This method controls the rate of false positives when multiple hypotheses are tested simultaneously. As such, FDR provides a moderate stringency that provides much more reliable results than simple T-statistics, but unlike the stringent Bonferroni correction, FDR will typically uncover some statistically significant differential expressions for further study.

2.2.8 **Gene Coverage and Analysis**

A more complete coverage of genes by microarrays can be expected to give a better foundation for global assessments and reconstruction of biochemical pathways. One obstacle here is that transcripts may be of low abundance, and thus be missed when looking for genes that are significantly differentially expressed and measurable above background intensities. Without addressing the problem of measuring transcripts with low abundance, complete assessment of the transcriptome cannot be achieved.

In the spirit of attaining a more complete coverage of nucleotide target sequences in an efficient, reproducible experimental system, all probe sequences should be present on the same array, so a single sample can be applied to the probe sequence cohort simultaneously. Future arrays should include, in order of increasing array density, the following:

1. Complete gene coverage (every gene represented at least once)
2. Complete transcriptome coverage (with all alternatively spliced forms)
3. Complete exon coverage (all possible exons)
4. Complete genome coverage (with representative probes evenly spaced throughout genome).

2.2.9 Sensitivity and Specificity

Amplification of target sequences continues to be used in instances where target samples are rare, such as with mammalian oocytes. There has previously been some concern that amplification, however, may skew the apparent abundance of transcripts, especially when multiple rounds of amplification are used. Multiple groups have addressed this problem, and with only a few rounds of linear amplification, reproducibility was found to be good.

Sensitivity of microarray measurements remains one of the largest technical concerns for acquiring comprehensive data. A better probe design is one way to approach the problem of low-abundance transcripts with measured intensities not significantly different from background levels, providing a way to increase measured signal intensity without corrupting the data. Knowledge of how probe qualities affect measurements also gives us the ability to grapple with the problem of deriving absolute abundance estimates from these measures. Current practice of hybridization on two-channel microarrays yields only information about *relative* changes in expression for the same gene between two different samples. To reconstruct genetic/biochemical networks from transcript data, however, knowledge of the *absolute* abundance of transcripts will be invaluable. Some attempts at making a conversion from measured fluorescence intensity have produced useful results, but these early efforts have not been widely applied to the diverse commercial and custom platforms used throughout the scientific community.

2.2.10 Spatial Resolution

The application of DNA microarrays can also address the question of *where* transcription occurs to the extent that tissues or cells of interest may be microdissected or otherwise separated from other tissues and cells before examination with a microarray. Combining laser capture microscopy and microarray analysis seems to offer a solution for this problem, but to have enough spatial resolution, a prohibitively large-number of arrays must be used. This requires the use of ISH techniques described below.

2.2.11 Large-scale ISH

One of the key strategies of investigating developmental processes is to examine the differential distribution of molecules as development progresses. To accomplish this with regard to transcripts, ISH is the most direct way to visualize tissue- or even subcellular-localization of transcripts. Some high-throughput ISH efforts have produced image databases of tremendous value to the scientific community, and efforts such as this are likely to accelerate in the near future with the recent development of robots and other technologies that streamline this laborious technique.

ISH uses hybridization of detectable probes to the transcripts of fixed tissues for the localization of gene expression and offers a characterization of gene expression that is complementary to the quantification of transcript abundance provided by DNA microarrays. Many tissues used in microarray studies are heterogeneous, or made up of several cell types, and so cell-type-specific enriched expression may be missed by microarray studies because of dilution within the heterogeneous tissue. Some tissues are difficult or presently impossible to separate by microdissection for applications in array experiments, so the ability to localize expression patterns to particular cell types should provide many insights inaccessible

to array experiments. Furthermore, cellular compartmentalization of transcripts is also generally not accessible to microarray studies, so ISH offers the ability to explore expression patterns at a higher resolution, which often provides insights that are invaluable for elucidating gene function. Probes with detectable tags attached are created either by synthesis of an oligo from a known sequence or by using PCR-amplified cDNA sequences of the target sequences.

Two recent reports described new gene expression atlases of human chromosome 21 orthologs in mouse at various developmental stages. In the first of these papers, researchers used an ISH robot they developed and an automated microscope to analyze about 6500 sections to generate their atlas covering E9.5, E10.5, E14.5, and adult tissues. Of the 178 confirmed human genes on chromosome 21, the researchers recorded expression for 98% of the 161 mouse orthologs. The second paper, by the HSA21 expression map initiative, describes efforts that examine mapping for 158 mouse homologs of human chromosome 21 confirmed genes (258 human chromosome 21 genes, 168 identified mouse cognates). Here, most of this group's emphasis was on mapping whole mount E9.5 embryos, although a subset of clones was mapped at other stages.

Each of these ISH mapping efforts has produced a freely available, high quality online database for retrieval of the ISH images and the supporting data and methods. Many new gene patterns of expression were discovered in each project. This work has provided an important resource for future work on any of the genes with transcripts mapped by these works.

2.3 Large-scale Analysis of Gene Expression at the Proteome Level

Proteomics, or the large-scale study of proteins, began in 1975, when the introduction of two-dimensional (2-D) electrophoresis allowed for the separation of and quantification of proteins by pI in the first dimension and by size in the second dimension. 2-D gels have been used in the creation of extensive databases cataloging spots and for measuring the differential expression of proteins. While work with 2-D gels is the classical definition of proteomics, large-scale yeast two-hybrid experiments and protein identification and detection of posttranslational modification by mass spectrometry (MS) techniques have joined this field. There are several computational techniques emerging to decipher metabolic networks, including the combination of yeast two-hybrid data with microarray studies to help define network topology. Additionally, efforts to create a "protein-chip" analogous to a DNA microarray are aimed to supplant the utility of 2-D gels.

One promising new technique is the use of matrix-assisted laser desorption ionization mass spectrometry (MALDI MS) of tissues that are laser capture microdissected (LCM) or contact blotted to characterize the spatial distribution of a large number of proteins in thin (~12 μm) tissue slices. MALDI MS techniques such as these join the ranks of immunohistochemistry and fluorescence microscopy for protein detection in tissues or cells, but MALDI MS presents an opportunity to achieve a much larger scale of analysis in a single experiment (hundreds of simultaneous protein measurements compared to one or a few simultaneous measures in the former techniques). MALDI MS

with contact-blotted tissues offers a spatial resolution of ~50 μm and has been used with striking results in sections of mouse brain and human glioblastomas.

2.4 Development and Evolution: Comparative Genomics

Recently it has become clear that many organisms share a similar mechanism of development; in many cases, genes that are conserved among species convey a similar function. For example, some transcription factors from one species can function in cells of other species after transfection.

One approach to finding genes and regulatory sequences essential for execution of a developmental plan is to compare the genomes of closely related species, looking for highly conserved sequences. The converse, looking for genes uniquely expressed in a developmental profile, may yield insights into how that profile generates the unique features of its developmental plan. The two forerunners for this kind of analysis are comparisons between *Drosophila* and *Anopheles*, and between *Mus musculus* and *Homo sapiens*. At this time, comparative genomics approaches have mainly been performed at the global level, without a published account detailing a comparison of genes with important developmental roles between genomes. Analysis of the current draft genomes with a focus on embryology has some beginnings in the supplemental materials accompanying the published comparative genomics of the *Drosophila* and *Anopheles* genomes, but we find little else that approaches this problem in the literature. This scarcity of ''comparative embryogenomics'' approaches is likely a consequence of our presently poor understanding of large regulatory networks for the specification of development. It is difficult to make comprehensive comparisons of the molecular details of development in different organisms without the corresponding network topologies to use as a conceptual framework of comparison.

It has been proposed by Meyerowitz that comparison of plant and animal developmental processes offers the only true comparative studies of development, as studies between animal species compare only developmental plans that are similar by descent. For example, segmental identity is established in *Drosophila* by spatially specific transcriptional activation of the HOX master regulatory genes. Vertebrates exhibit similar processes in the developing brain. *Arabidopsis*, however, has master regulatory genes, mainly in the MADS family (named for the founding family members Mcm1, Agamous, Deficiens, and serum response factor (SRF)), but these sequences have no similarity to the *HOX* genes. A second pattern specification in animals, the dorsal-ventral specification, has a logical analog in plant, but most of the animal genes involved in this specification are absent in plants. Gurken, the receptor tyrosine kinases, Ras protein, and Pipe, which are all implemented in the dorsal-ventral specification in *Drosophila*, have no homologs in plants. Adaxial–abaxial axes in the leaves of Arabidopsis, the final example of pattern formation given by Meyerowitz, involves activation of the YABBY (named for the australian fresh water crayfish (''yabby'') as a link to Crabs claw, the founding member of the gene family) family of transcription factors by the GARP (glycoprotein A repetitions predominant) family of transcription factors. No animal genomes are known to encode members of the YABBY or GARP protein families, again demonstrating the lack of molecular similarity between patterning in

these two kingdoms. Plants and animals have a very different molecular specification for pattern formation, but the logic of that patterning has striking similarity. This relationship presents an opportunity for ''true'' comparative developmental studies where the focus of study will be how similar logical patterning is achieved with a different molecular toolset.

Now that draft genomes for human and mouse are available, comparative genomics approaches should yield valuable insights into development. The mouse and human genomes have 217 syntenic blocks, from 303 kb to 64.9 Mb in size. 90.2% of the human genome and 93.3% of the mouse genome compose these syntenic regions. While much comparative analysis was completed with the publication of the mouse genome, there was no special attention given to developmental processes in this analysis.

2.5 Functional Genomics/Large-scale Manipulation of Expression

2.5.1 Mutagenesis

The availability of mutant model organisms underpins much of our understanding about development and disease. For the mouse, less than 5% of genes have been mutated, although there are several large-scale mutagenesis projects underway. Most of these mutations were created as targeted mutagenesis by homologous recombination in ES cells. While targeted mutations offer precise selection of the gene to mutate, the standard strategy causes the creation of a null allele. It is often preferable to generate point mutations that may have a range of effects, as this provides more knowledge about protein function. Chemical mutagenesis strategies have the advantages that they allow for phenotype screening, which may be preferable to targeting a specific gene, and they can produce point mutations that have a spectrum of effects on protein function.

Mutagenesis by X-ray, chlorambucil (CHL), and ethylnitrosurea (ENU) all produce random genomic mutations. X-rays produce large mutations and has a low efficiency. CHL also creates large deletions, but creates mutations more efficiently. ENU has the advantage that it creates point mutations. ENU causes ethylation of either O or N, with the most frequent base pair changes being A/T→T/A (44%), A/T→G/C (38%), and G/C→A/T (8%), most of which are missense mutations (64%). ENU is used with the idea of affecting the early spermatogonial cells of male mice, so these males will produce mutated sperm for the remainder of their lives (after a period of sterility).

2.5.2 Gene Trapping

Gene trapping is a technique that permits reverse genetics and provides a mechanism that does not require additional steps to isolate the gene responsible for the phenotype of interest. The principle method of gene trapping is to randomly insert a promoterless construct with reporter, selectable marker, and splice site(s) into the genome. Proper integration and splicing of this construct will result in the creation of a fusion protein with one or more exons of the trapped locus and, ideally, the native transcript is truncated, so it will be nonfunctional.

Constructs with a splice acceptor (SA) or both a SA and a splice donor (SD) are the most commonly used gene trap vectors. The murine engrailed-2 and the adeno virus late major transcript SA are both widely used, and the human *BCL-2* gene intron 2/exon 3 SA has been introduced more recently. One potential problem is

that typical reporters are only detectable if the insertion is in-frame, but with gene-trapping the insertion of the trapping vector is random. Reporter activity is enhanced by the insertion of an internal ribosomal entry site (IRES) between the SA and the reporter in the gene trap vector. The IRES allows independent translation of the reporter, and thus reporter detection does not require in-frame gene trapping when the gene trap vector contains an IRES.

2.5.3 RNAi/siRNA

RNA interference (RNAi) is perhaps the most exciting technology introduced to molecular biology in recent years. RNAi takes advantage of cellular mechanisms that carry out the destruction of specified transcripts and may provide a loss-of-function phenotype, thus providing insights and motivation for further analysis. Before the application of RNAi, gene knockouts and knockdowns could take many months or even years to achieve useful results. Now, large-scale transient inactivation of individual genes (in *Caenorhabditis elegans*, for example) can be achieved for thousands of genes (separately) in a few months (see Sect. 3.1.3).

Briefly, the mechanism of RNAi begins in the cell with the introduction of double-stranded RNA (dsRNA), which mediates interference with the target of interest. Short interfering RNAs (siRNAs), 21- to 23-nt, are produced by the cutting action of the enzyme Dicer on dsRNA. The siRNAs are incorporated into the RNAi-induced silencing complex (RISC), which is a multisubunit protein complex. The RISC may unwind the siRNA, thus facilitating interaction with the target transcript. Those siRNAs that interact with targets lead to target cleavage by DICER and liberate new siRNA as a result. The remaining mRNA target is degraded by exonucleases. It also seems likely that siRNA can act as a primer for an RNA-dependent polymerase (RdRP), which would allow for the amplification of siRNA sequences. The positive feedback loop provided by an RdRP could explain how a relatively small amount of siRNA can cause the degradation of a larger amount of target and how it is that RNAi is inheritable in worms.

RNAi may be applied to many eukaryotic systems, but of the metazoans, *C. elegans* is particularly well suited for this approach because these worms may be fed bacteria transfected with the dsRNA used as an RNAi stimulus.

3 Model Organisms for Embryogenomics

Model organisms are chosen in order to optimize suitability for a particular type of investigation and the utility of the knowledge gained in the study. By ''suitability,'' we mean the accessibility of the organism's physiology to investigation, including considerations such as gestation period, physical properties of the body tissues of interest, and overall effort required in maintenance of the organism. Utility of the knowledge gained refers to the closeness of the model organism's genetics and physiology to the organism (or more generally, organisms) we are modeling (for example, Homo sapiens). Here we discuss the various model organisms studied in embryology using genomics approaches. We will consider the advantages and disadvantages of the various model organisms, and review the current status of genomics approaches to developmental questions. Each organism discussed here has a rich history as a model for developmental studies and so our discussions will necessarily be cursory and highlight

the salient features of each organism and their place in the study of development in general and in embryogenomics.

3.1 Non-mammalian Animals

3.1.1 Drosophila Melanogaster

The developmental stages of metamorphosis in the fruit fly *Drosophila melanogaster*, hereafter *Drosophila*, are the first developmental plans to be studied with microarray analysis. *Drosophila* has a small genome, an extremely short life cycle, and is relatively inexpensive to maintain, which makes this organism appealing for use in scientific investigations. *Drosophila* has been the most powerful system for genetic analysis with the ease of mutant screening and the large archives of such mutants. Completion of the *Drosophila* genome has increased the value of this model species further. There is a large body of experimental knowledge about development in *Drosophila* and over 125 000 cDNA clones from *Drosophila* have been derived from embryonic stages (Table 1). Systematic large-scale ISH of 2179 genes has also been reported recently.

3.1.2 Anopheles Gambiae

The genome sequencing of the malaria mosquito, *Anopheles gambiae,* hereafter *Anopheles,* was published in 2002, thus providing the opportunity to compare the genomes of the two dipteran species *Drosophila* and *Anopheles*. Prior to the availability of this genome sequence, interest in *Anopheles* was primarily focused on the prevention and treatment of malaria. Although there has been interest in the life cycle of *Anopheles*, this has mainly been with the goal of understanding the corresponding life cycle of *Plasmodium falciparum* (the malaria-causing organism that invades erythrocytes) better, and there are no cDNA libraries with sequences in dbEST that report derivation from *Anopheles* embryonic stages.

Comparative genomics analysis of *Anopheles* and *Drosophila* appeared in a companion paper to the *Anopheles* draft genome paper. Although most of this analysis emphasized a global comparison, the supplementary materials for this work included a simple analysis of some developmentally important genes. Flybase (*Drosophila*) was queried with keywords related to embryos and development to identify 314 *Drosophila* genes (after manual corrections), and the orthologs in *Anopheles* were identified. This information was placed in a table according to *Drosophila* gene name, and the number of *Anopheles* orthologs was listed. This procedure demonstrated that most of the characterized *Drosophila* genes listed that are important in development had orthologs in *Anopheles* (88%), whereas ~12% of these developmentally important genes appear to be absent in *Anopheles*. This analysis offers some clues about genes that may drive important differences in the developmental plan of *Drosophila*. The absence of the reciprocal analysis underscores that there is much less gene information available for *Anopheles*.

3.1.3 Caenorhabditis Elegans

Caenorhabditis elegans, hereafter *C. elegans*, has been of profound importance for developmental studies, primarily because it has been possible to follow the developmental lineage and migration of every cell in the organism from one cell through adulthood.

In addition to the usefulness of *C. elegans* in small-scale functional studies of development, this organism has proved useful beyond its anticipated advantages as a model organism because of the application

Tab. 1 EST sequences (S) and unique clones (C) reported for cDNA libraries by NCBI unigene (as of July 18, 2003).

of RNAi. *C. elegans* may be fed bacteria carrying RNAi vectors, and these vectors can cause the destruction of targeted native transcripts in the worm. Kamath, et al. have recently performed a comprehensive functional analysis of *C. elegans* using RNAi. By their count, there are 19 427 predicted genes in *C. elegans*, and they inhibited transcript function for 16 757 (about 86%) of this total. 1528 single-gene mutant phenotypes were identified, where a mutant phenotype was defined as reproducible sterility, embryonic or larval lethality, slow postembryonic growth, or any of a number of specifically defined postembryonic defects. This work also established that there is high reproducibility of RNAi techniques, regardless of methods, and showed there is a false positive rate of <1%. Kamath, et al. claim to have identified more than 70% of all embryonic lethal phenotypes in *C. elegans*. Their efforts have produced both an intellectual contribution and a tremendous resource for the scientific community.

3.1.4 Xenopus Laevis

Xenopus laevis has been of value to embryology in the areas of early fate decisions and morphogenesis (with detailed fate maps constructed for blastula and from gastrula through organogenesis), patterning of the vertebrate body plan, and early organogenesis. Moreover, several functional genomics studies have focused on *X. laevis* development. When females are injected with human chorionic gonadotropin, they ovulate and lay hundreds of oocytes that may be manipulated or subjected to *in vitro* fertilization. The early embryos are quite large and are thus suitable for microinjections and dissections. The embryos are also transparent, thus making the effects of experimental conditions easy to visualize. Recently, *X. tropicalis* has been identified as a model system that retains the advantages of *X. laevis*, but has the additional benefits of having a diploid genome suitable for genetics study and a shorter generation time, making this species more accessible to multigenerational approaches.

3.1.5 Brachydanio Rerio

The zebrafish *Brachydanio rerio*, hereafter *Danio*, has been a cornerstone model organism for developmental processes because *Danios* are extremely hardy and easy to raise, a large number of *Danio* mutants have been created by mutagenesis, and most importantly, *Danio* embryos are transparent, thereby facilitating their study by noninvasive observation. Large-scale ISH has been done to identify genes specific to embryonic stages in *Danios*. There are more than 34 000 cDNA clones derived from *Danio* embryos available (Table 1). Recently, the first cDNA microarray constructed from *Danio* cDNA libraries, including a library derived from three-day-old embryonic heart, has been used to study development and hypoxia.

3.1.6 Strongylocentrotus Purpurratus

The long history of the sea urchin as a developmental model has its beginnings with the discovery by Theodore Boveri that chromosomes contain information for controlling the development of embryos. Of the developmental plans in the metazoans, only the sea urchin endomesoderm specification has been reconstructed from existing experimental knowledge. This tremendous effort combined many years of acquired experimental knowledge with computer simulation to construct what Davidson, et al., describe as a provisional model for the specification of the endomesoderm in *Strongylocentrotus purpurratus*.

3.2 Mammalian

Studies of mammalian systems are expected to offer the most relevant insights into human developmental processes. We begin our discussion of mammalian model organisms with a look at human, mouse, and rat as systems for inquiry into developmental questions. Moral and practical considerations severely restrict studies with human tissues, so the emphasis of our discussion will be on the nonhuman mammals, *Mus musculus* and *Rattus norvegicus*, with most of our attention on *Mus musculus*, the preeminent model organism that most closely matches human developmental patterns.

3.2.1 Homo Sapiens

Mammalian species are of greatest interest to embryonic investigations because the traditional view is that these species will provide the most relevant model for the human. Ethical concerns limit the availability of human embryonic tissues and essentially forbid any *in vivo* embryological experimentation. Despite these limitations, several large-scale experimental studies have been performed using human embryo tissues, and there is great interest in studies with stem cells derived from human. The human draft genome sequence was made available in 2001 and the completed human genome was announced in March 2003, although new analysis of the present sequence has not been published as of this writing. The recent availability of the mouse genome will greatly contribute to our understanding of regulatory elements and conserved genes important to development by comparison with the human sequence.

3.2.2 Mus Musculus

The house mouse *Mus musculus* is the forerunner of model organisms for use in studies of development and pluripotency. Similarity to human development, short generation time, and the relatively low cost of maintenance all contribute to the notion that *Mus musculus* is the optimal model organism for relevant and rapid large-scale developmental investigations. Of mouse, rat, and human, only mouse has cDNA libraries derived from preimplantation stage embryos. Transcript expression specific to these early embryonic stages may be overlooked in rat and human because of the difficulty in working with and acquiring these rare tissues. Another advantage of the mouse as a model is that the largest number of full-length cDNA clones have been assembled and sequenced for mouse.

In response to the underrepresentation of embryonic tissues in cDNA collections, many new libraries have been created from these rare tissues in mouse. The availability of over 115 000 cDNA clones derived from preimplantation tissues in mouse offer a compelling reason to choose a mouse model for study of early development. Sequencing and subsequent analysis has identified many novel or rare transcripts from early embryonic stages. Given multiple EST sequences from these libraries, an effort to assemble collections of representative transcripts culminated in the construction of the NIA Mouse 15K and NIA Mouse 7.4K cDNA collections. Each of these collections has been distributed worldwide to more than 100 cDNA microarray facilities and these clones are used in both spotting cDNA microarrays and in downstream functional studies.

The human and mouse genomes together represent valuable tools for comparative studies, revealing important *cis*

regulatory elements, definition of gene structures, and key genes for shared developmental processes. The draft sequence and analysis of the mouse genome was published recently. 1859 Mb of the sequence is draft sequence (74%) and 477 Mb is finished sequence (19%) for a total mouse genome size of 2.5 Gb (Human, 2.9 Gb). Over 96% of the assembled nucleotides have only about 1 mismatch per 10 000 bases. When finished bacterial artificial chromosome (BAC) sequences were compared to the assembly, the discrepancy rate was 0.005%, corresponding to about 1 mismatch per 20 000 bases. Comparisons of the high quality mouse and human genomes underscore the usefulness of comparative studies. For example, the Sox family of transcription factors is important to many developmental processes in both mouse and human and includes the *Sry* gene on the Y chromosome, which specifies testis determination. A comparative analysis of the human and mouse genomes has determined the precise number and ortholog identity of the members of Sox family of transcription factors, thus resolving the nomenclature for this important family of genes.

The utility of dsRNA for RNAi in mouse oocytes and preimplantation embryos has been demonstrated. It was shown that dsRNA could be used to prevent gene expression of a GFP transgene (MmGFP) in heterozygotes where the transgene was parentally derived. Two-cell expression of the GFP transgene was prevented by injection of dsRNA MmGFP in the one-cell zygote. This work showed that strong, specific depletion of target transcripts could be achieved from the four- to six-cell stage through the blastocyst stage. It was later demonstrated that hairpin RNA could achieve similar results. For these promising techniques, the main difficulty is that injection of the RNAi vector is required in each instance. This difficult procedure currently limits the extent of the application of RNAi in these early embryonic tissues, and poses a challenge to any present notion of making this procedure large scale.

3.2.3 Rattus norvegicus and others

The first genome assembly of *Rattus norvegicus*, hereafter rat, was recently announced by the Rat Genome Sequencing Consortium (announcement June 19, 2003). The rat genome is slightly larger than the mouse genome (2.57 Gb compared to 2.5 Gb). Details of the assembly, as well as comparative genomics of rat to another species, awaits future publication as of this writing. Rat is primarily used as a model organism for cardiovascular or physiological research, but the availability of genome sequence may spark interest in comparative genomics approaches toward a better understanding of the common features of genetic programs of development among mammals. Similarly, genome projects for other mammals or vertebrates (Fig. 1) may also spark interest in large-scale comparative studies of development.

3.3 Plants

Plant embryology enters our discussion because although plant and animal development and physiology are quite distinct at the molecular level, many of the experimental procedures and analysis share common techniques and strategies for elucidation of developmental pathways. There is also the additional motivation that comparative studies between plant and animal development may yield evolutionary insights and provide clues about

convergence of some aspects of their developmental plans (see Sect. 2.4).

3.3.1 Arabidopsis Thaliana

Completion of genome sequencing for the thale cress *Arabidopsis thaliana* has strengthened the utility of this plant model for comparative approaches to development. Arabidopsis has long been of interest for genomics and developmental studies because of its small genome and short germination and development cycle. Of plants, *Arabidopsis* is the canonical species for large-scale studies.

3.3.2 *Zea Maize* and Others

Crop plants like *Zea maize* (corn) and *Orzo sativa* (rice) are heavily studied because of their importance as a food source for much of the world. Genome projects for each of these organisms are progressing and will contribute to the comparative genomics approaches between plants and the more general comparisons of development between kingdoms.

3.4 Suitability of Approaches for Particular Model Organisms Applied to the Study of Development

The traditional view has been that mammalian systems are closest to the human in genome organization and developmental plan, so these systems are of greatest interest as model species. The biggest trade-off here is that viviparity makes mammalian systems much more difficult to work with than egg-laying organisms. The increased cost and effort involved in working with mammalian systems provides incentive for working with other organisms that are more suitable for some large-scale efforts. For example, the nematode *C. elegans* has been an apt choice for developmental studies including large-scale mutagenesis for many years. More recently, *C. elegans* is the first metazoan to be extensively studied using RNAi to selectively render transcripts nonfunctional.

The primary benefits of the mouse as a developmental model are the closeness of developmental plan to that of the human and the availability of a large number of cDNA clones throughout the preimplantation stages and later embryo development. *C. elegans* offers a rich base of experimental knowledge, relatively easy application of RNAi, a large number of available mutants, and easy maintenance. *Xenopus* offers a replenishable source of oocytes and a large oocyte ($\sim$1 mm) that may be collected and manipulated relatively easily. *Danios* offer a rich base of experimental knowledge, a large number of available mutants, a translucent embryo for easy visualization of development, and are easily maintained.

4 Summary Remarks

Embryogenomics presents an exciting new area that continues to grow and draw great interest from the scientific community. Although there are some difficulties with current hardware and analysis technologies, these issues are being aggressively addressed in an effort to approach the attractive goal of effective systems biology approaches that yield accurate predictions that guide our understanding of development and provide fertile ground for future investigations.

Prion
Proteinaceous infectious particle.

PrP^C
Normal isoform of the prion protein.

PrP^{Sc}
Disease-causing isoform of the prion protein.

Prions are infectious proteins that have been described in both mammals and fungi. That prions are composed solely of proteins makes them unprecedented infectious pathogens. Prions are proteins that can adopt at least two different conformations; they multiply by forcing the precursor protein to acquire a second conformation. Different conformations of proteins in the prion state encipher distinct strains and are prone to aggregation. In mammals, prions accumulate to high levels in the nervous system where they cause dysfunction and fatal degeneration.

Both mammalian and fungal prions have been produced in cell-free systems. Synthetic prion protein (PrP) peptides and recombinant PrP fragments have been used to form mammalian prions while N-terminal regions, called *prion domains* that are rich in glutamine and asparagine, have been used to form fungal prions.

Prions cause a group of invariably fatal, neurodegenerative diseases. Prion diseases may present as genetic, infectious, or sporadic disorders, all of which involve modification of PrP. The tertiary structure of PrP is profoundly altered as prions are formed, and as such, prion diseases represent disorders of protein conformation. Creutzfeldt-Jakob disease (CJD) generally presents as a progressive dementia in humans while scrapie of sheep and bovine spongiform encephalopathy (BSE) usually manifest as ataxic illnesses.

1
Prions

In mammals, prions reproduce by recruiting the normal, cellular isoform of the prion protein (PrP^C) and stimulating its conversion into the disease-causing isoform (PrP^{Sc}). PrP^C has a high α-helical content and little β-sheet structure, whereas PrP^{Sc} has less α-helical structure and a high β-sheet content. Comparisons of secondary structures of PrP^C and PrP^{Sc} were performed on proteins purified from Syrian hamster (SHa) brains. Limited proteolysis of PrP^{Sc} produces PrP 27–30, which retains prion infectivity; under these conditions, PrP^C is completely hydrolyzed (Fig. 1).

Solution structures of recombinant SHa and mouse (Mo) PrPs produced in bacteria showed three α-helices denoted A, B, and C as well as two short β-strands using nuclear magnetic resonance (NMR) imaging. The atomic structure of PrP^{Sc} has not been determined because of the insolubility of the protein. Two-dimensional crystals of PrP 27–30 have been used to constrain computational models of PrP^{Sc} suggesting it contains α-helix C and a portion of α-helix B while α-helix A, the two β-strands, and the surrounding segments form a β-helix. From these studies as well as from ionizing radiation inactivation analyses, it is likely that the infectious monomer is a trimer of PrP^{Sc} molecules. Recombinant

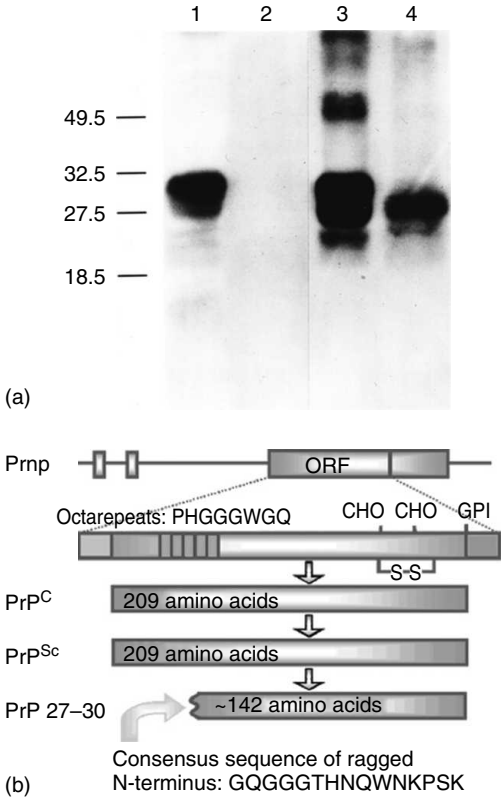

Fig. 1 Prion protein isoforms. Western immunoblot of brain homogenates from uninfected (lanes 1 and 2) and prion-infected (lanes 3 and 4) Syrian hamsters. Samples in lanes 2 and 4 were digested with 50 µg mL^{-1} of proteinase K for 30 min at 37 °C. PrP^C in lanes 2 and 4 was completely hydrolyzed under these conditions, whereas approximately 67 amino acids were digested from the N-terminus of PrP^{Sc} to generate PrP 27–30. After polyacrylamide gel electrophoresis (PAGE) and electrotransfer, the blot was developed with anti-SHaPrP R073 polyclonal rabbit antiserum. Molecular weight markers are depicted in kilodaltons (kDa). (b) Bar diagram of the SHaPrP gene that encodes a protein of 254 amino acids. After processing of the N- and C-termini, both PrP^C (green) and PrP^{Sc} (red) consist of 209 residues. After limited proteolysis, the N-terminus of PrP^{Sc} is truncated to form PrP 27–30, which is composed of approximately 142 amino acids, the N-terminal sequence of which was determined by Edman degradation. (See color plate p. xxvii).

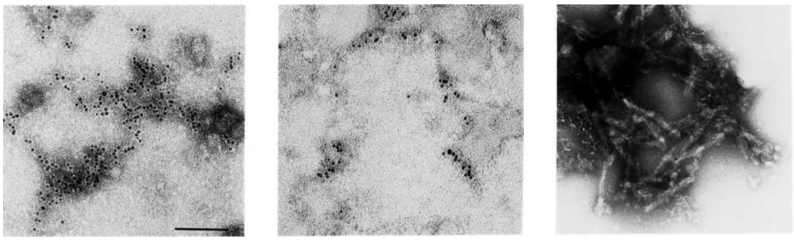

Fig. 2 Electron micrographs of negatively stained and immunogold-labeled prion proteins. (a) PrP^{C} and (b) PrP^{Sc}. Neither PrP^{C} nor PrP^{Sc} forms recognizable, ordered polymers. (c) Prion rods composed of PrP 27–30 were negatively stained. The prion rods are indistinguishable from many purified amyloids. Bar = 100 nm. Reprinted with permission, from (Pan, K-M., Baldwin, M., Nguyen, J., Gasset, M., Serban, A., Groth, D., Mehlhorn, I., Huang, Z., Fletterick, R.J., Cohen, F.E., Prusiner, S.B. (1993) Conversion of α-helices into β-sheets features in the formation of the scrapie prion proteins, *Proc. Natl. Acad. Sci. U. S. A.* **90**, 10962–10966), copyright 1993 National Academy of Sciences, USA.

antibody fragments have been used to map the surfaces of PrP^{C} and PrP^{Sc} and those results are consistent with the foregoing structural data. The structural transition from an α-helical protein into a β sheet–rich molecule seems to be the fundamental event underlying the formation of nascent prions.

Limited proteolysis truncates the N-terminus of PrP^{Sc} to produce PrP 27–30 consisting of the C-terminal ~142 amino acids. PrP 27–30 polymerizes into amyloid fibrils that are indistinguishable from fibrils found in amyloid plaques of the brains of mammals with prion disease. When full-length PrP^{Sc} was purified from SHa brain, only amorphous aggregates were seen by electron microscopy. While limited digestion of purified PrP^{Sc} with proteinase K produced PrP 27–30, the ultrastructural appearance of the samples remained unchanged (Fig. 2). Addition of a detergent, such as Sarkosyl, either before or after limited proteolysis provoked the assembly of PrP 27–30 into rod-shaped structures with the ultrastructural and tinctorial properties of amyloid.

2 Prions are Distinct from Viruses

Major features that distinguish prions from viruses are: (1) the ability to create prion infectivity by modifying the conformation of a polypeptide devoid of nucleic acid and (2) PrP is encoded by a chromosomal gene, designated *PRNP* in humans and *Prnp* in mice. The PrP gene is located on the short arm of chromosome 20 in humans and the syntenic region of chromosome 2 in mice.

Prions differ from viruses and viroids in that they lack a nucleic acid genome that directs the synthesis of their progeny. Many investigators argued for a nucleic acid genome within the infectious prion particle while others contended for a small, noncoding polynucleotide of either foreign or cellular origin. No nucleic acid has been found despite intensive searches using a wide variety of techniques and approaches. On the basis of a wealth of evidence, it is reasonable to assert that such a nucleic acid has not been found because it does not exist. Prions are composed of an

alternative isoform of a cellular protein, whereas most viral proteins are encoded by a viral genome and viroids are devoid of protein.

In contrast to viruses, prions are nonimmunogenic. Prions do not elicit an immune response because the host is tolerant to PrP^{C}, which prevents the host from mounting an immune response to PrP^{Sc}. In contrast, foreign proteins of viruses that are encoded by the viral genome often elicit a profound immune response. Thus, it seems unlikely that vaccination, which has been so effective in preventing many viral illnesses, will be a useful strategy for preventing or treating prion diseases.

When prions and viruses are passaged from one host species to another, the consequences are very different. The passage of prions from one host to another is accompanied by the acquisition of a new PrP amino acid sequence encoded by the genome of the new host. The crossing of prions from one species to another is restricted by what has been called the ''species barrier''. The closer the evolutionary relationship is between the host in which the prions last replicated and the newly infected animal, the more likely replication will occur in the new host. However, particular strains of prions can change this rule. For example, variant CJD prions from humans replicate much more readily in transgenic (Tg) mice expressing bovine (Bo) PrP than in Tg mice expressing human or chimeric mouse-human PrP.

The issue of prion strains posed a profound conundrum for many years. How could an infectious pathogen composed only of protein encipher biological information? This riddle was solved when prion strains with different physical properties were isolated. Subsequently, new strains of prions have been isolated either by passage through mice expressing artificial PrP transgenes or by forming synthetic prions from PrP produced in *Escherichia coli*.

3 Disease Paradigms

Despite some similarities between prion and viral illnesses, these disorders are very different. Prion diseases are uniformly fatal. No human or animal has ever recovered from a prion disease once neurologic dysfunction is manifest. No host defenses are mounted in response to prion infection: no humoral immunity, no cellular immunity, and no interferons are elicited to the replicating prion.

While prions can be spread from one host to another, the most common form of prion disease is spontaneous or sporadic. In these illnesses, prions arise endogenously and replicate. Recent experiments with synthetic prions demonstrate that only PrP^{C} is required to generate prion infectivity. These findings contrast with viruses in which exogenous infection is required except in the case of latent retroviral genomes. For example, after infection with exogenous HIV, the virus may disappear but its RNA genome may be reverse-transcribed into DNA and the DNA copies may remain dormant for years.

The dramatically different principles that govern prion biology have often been poorly understood. This lack of understanding has led to some regrettable decisions of great economic, political, and possibly public health importance. For example, scrapie and BSE have different names, yet they are the same disease in two different species. Scrapie and BSE differ in only two respects: first, the PrP sequence in sheep differs from that of cattle at seven

or eight positions of 270 amino acids, which results in different PrP^{Sc} molecules. Second, some aspects of each disease are determined by the particular prion strain that infects the respective host.

Understanding prion strains and the ''species barrier'' is of paramount importance with respect to the BSE epidemic in Britain, in which more than 180 000 cattle have died over the past decade. Brain extracts from eight cattle with BSE resulted in similar incubation times and patterns of vacuolation in the neuropil when inoculated into a variety of inbred mice. Incubation times and profiles of neuronal vacuolation have been used for three decades to study prion strains. Brain extracts prepared from three domestic cats, one nyala, and one kudu, all of which died of a neurologic illness, produced incubation times and lesion profiles indistinguishable from those found in the BSE cattle. Cats and exotic ungulates (such as the kudu) presumably developed prion disease from eating food containing bovine prions.

4 Nomenclature

Although the prions that cause transmissible mink encephalopathy (TME) and BSE are referred to as *TME prions* and *BSE prions*, this may be unjustified because both are thought to originate from the oral consumption of scrapie prions in sheep-derived foodstuffs and because many lines of evidence argue that the only difference among various prions is the sequence of PrP, which is dictated by the host and not the prion itself. Human (Hu) prions present a similar semantic conundrum. Transmission of Hu prions to laboratory animals produces prions carrying PrP molecules with sequences dictated by the PrP gene of the last host, not that of the inoculum.

To simplify the terminology, the generic term PrP^{Sc} was suggested in place of such terms as PrP^{CJD}, PrP^{BSE}, and PrP^{res}. To distinguish PrP^{Sc} found in humans and cattle from that found in other animals, ''$HuPrP^{Sc}$'' and ''$BoPrP^{Sc}$'' are suggested instead of PrP^{CJD} and PrP^{BSE}, respectively. Once human prions, or $HuPrP^{Sc}$ molecules, have been passaged into animals, the prions and PrP^{Sc} are no longer of the human species unless they were formed in an animal expressing a HuPrP transgene.

The ''Sc'' superscript of PrP^{Sc} was initially derived from the term ''scrapie'' because scrapie was the prototypic prion disease. Because all of the known prion diseases (Table 1) of mammals involve aberrant metabolism of PrP similar to that observed in scrapie, the ''Sc'' superscript was suggested for all abnormal, pathogenic PrP isoforms. In this context, the ''Sc'' superscript is used to designate the disease-causing isoform of PrP (Table 2). The development of the conformation-dependent immunoassay (CDI) for PrP^{Sc} led to the discovery of a protease-sensitive form of PrP^{Sc}, designated $sPrP^{Sc}$. The CDI is based on measuring antibody binding to an epitope that is exposed in PrP^{C} but buried in PrP^{Sc}. Under conditions of limited proteolysis in which the protease-resistant form of PrP^{Sc}, designated $rPrP^{Sc}$, is converted into PrP 27–30, $sPrP^{Sc}$ is completely hydrolyzed. Whether $sPrP^{Sc}$ is an intermediate in the formation of infectious prions remains to be established.

In the case of mutant PrP, mutations and polymorphisms can be denoted in parentheses following the PrP isoform.

Tab. 1 The prion diseases.

Disease	*Host*	*Mechanism of pathogenesis*
Kuru	Fore people	Infection through ritualistic cannibalism
Iatrogenic CJD	Humans	Infection from prion-contaminated HGH, dura mater grafts, etc.
Variant CJD	Humans	Infection from bovine prions?
Familial CJD	Humans	Germline mutations in PrP gene
GSS	Humans	Germline mutations in PrP gene
FFI	Humans	Germline mutations in PrP gene (D178N,M129)
Sporadic CJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
sFI		Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
Scrapie	Sheep	Infection in genetically susceptible sheep
Bovine spongiform encephalopathy	Cattle	Infection with prion-contaminated MBM
Transmissible mink encephalopathy	Mink	Infection with prions from sheep or cattle
Chronic wasting disease	Mule deer, elk	Unknown
Feline spongiform encephalopathy	Cats	Infection with prion-contaminated bovine tissues or MBM
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

Notes: CJD: Creutzfeldt–Jakob disease; FFI: fatal familial insomnia; sFI: sporadic fatal insomnia; GSS: Gerstmann–Sträussler–Scheinker disease; HGH: human growth hormone; MBM: meat and bone meal.

For fatal familial insomnia (FFI), in which it might be important to identify the mutation, the prions would be designated $HuPrP^{Sc}$(D178N,M129) (Table 3).

Parentheses following PrP^{Sc} can also be used to notate a particular prion strain. For example, prions from Syrian hamsters inoculated with Sc237 or 139H prion strains can be designated $SHaPrP^{Sc}$(Sc237) or $SHaPrP^{Sc}$(139H), respectively. Similarly, sheep inoculated with scrapie or BSE prions produce $OvPrP^{Sc}$(Sc) or $OvPrP^{Sc}$(BSE), respectively.

The terms "PrP^{res}" and "PrP-res" were derived to describe the protease resistance of PrP^{Sc} and have sometimes been used interchangeably with PrP^{Sc}. The use of "PrP^{res}" and "PrP-res" became particularly problematic with the discovery of $sPrP^{Sc}$. Protease resistance, insolubility, and high β-sheet content should be considered only as surrogate markers of PrP^{Sc} infectivity because not all characteristics may be present. For example, $MoPrP^{Sc}$(P101L) from Tg mice that express high levels of MoPrP(P101L) is transmissible to Tg(MoPrP,P101L)196/$Prnp^{0/0}$ mice, but these prions are sensitive to proteolytic digestion at 37 °C. When digestions were performed at 4 °C or the CDI was used to detect PrP^{Sc}, then $MoPrP^{Sc}$(P101L) was detected. In contrast, when Tg196 mice were inoculated with mouse RML prions, the resulting $MoPrP^{Sc}$(P101L) was resistant to proteolytic digestion at 37 °C. These

Tab. 2 Glossary of prion terminology.

Term	*Description*
Prion	A proteinaceous infectious particle that lacks nucleic acid. Prions are composed largely, if not entirely, of PrP^{Sc} molecules.
PrP^{Sc}	Abnormal, pathogenic isoform of the prion protein that causes illness. This protein is the only identifiable macromolecule in purified preparations of prions.
PrP^{C}	Cellular isoform of the prion protein.
PrP 27–30	N-terminally truncated PrP^{Sc}, generated by digestion with proteinase K.
PRNP	Human PrP gene located on chromosome 20.
Prnp	Mouse PrP gene located on syntenic chromosome 2. *Prnp* controls the length of the prion incubation time and is congruent with the incubation-time genes *Sinc* and *Prn-i*. PrP-deficient ($Prnp^{0/0}$) mice are resistant to prion infection.
PrP amyloid	Fibril of PrP fragments derived from PrP^{Sc} by proteolysis. Plaques containing PrP amyloid are found in the brains of some mammals with prion disease.
Prion rod	An amyloid polymer composed of PrP 27–30 molecules. Created by detergent extraction and limited proteolysis of PrP^{Sc}.
Protein X	A hypothetical macromolecule that is thought to act as a molecular chaperone in facilitating the conversion of PrP^{C} into PrP^{Sc}.

Tab. 3 Examples of human PrP gene mutations found in the inherited prion diseases.

Inherited prion disease	*PrP gene mutation*
Gerstmann–Sträussler–Scheinker disease	P102L[a]
Gerstmann–Sträussler–Scheinker disease	A117V
Familial Creutzfeldt–Jakob disease	D178N, V129
Fatal familial insomnia	D178N, M129[a]
Gerstmann-Sträussler-Scheinker disease	F198S[a]
Familial Creutzfeldt–Jakob disease	E200K[a]
Gerstmann–Sträussler–Scheinker disease	Q217R
Familial Creutzfeldt–Jakob disease	octarepeat insert[a]

[a]Signifies genetic linkage between the mutation and the inherited prion disease.

findings emphasize the ambiguities that may arise from simply assessing resistance to proteolytic digestion. Whether PrP^{res} is useful in denoting PrP molecules that have been subjected to procedures modifying resistance to proteolysis but that neither convey infectivity nor cause disease remains questionable. Perhaps PrP^{res} is best reserved for PrP molecules that exhibit resistance to limited proteolysis after binding to PrP^{Sc}.

The term "PrP*" has been used in two different ways. First, it has been used to identify a fraction of PrP^{Sc} molecules that are infectious. Such a designation is thought to be useful because

there are $\sim 10^5$ PrP^{Sc} molecules per infectious (ID_{50}) unit. Second, PrP* has been used to designate a metastable intermediate of PrP^C that is bound to a putative conversion cofactor, provisionally designated protein X. It is noteworthy that neither a subset of biologically active PrP^{Sc} molecules nor a metastable intermediate of PrP^C has been identified, to date.

In mice, *Prnp* is now known to be identical to two genes, *Sinc* and *Prn-i,* that are known to control the length of the incubation time in mice inoculated with prions. A gene, designated *Pid-1,* on mouse chromosome 17 also appears to influence experimental CJD and scrapie incubation times but information on this locus is limited.

Distinguishing among CJD, FFI, and Gerstmann–Sträussler–Scheinker syndrome (GSS) has grown increasingly difficult with the recognition that familial (f) CJD, GSS, and FFI are autosomal-dominant diseases caused by mutations in *PRNP* (Table 3). Initially, it was thought that each *PRNP* mutation was associated with a particular cliniconeuropathologic phenotype, but more exceptions are being recognized. Multiple examples of variations in the cliniconeuropathologic phenotype have been recorded within a single family in which all affected members carry the same *PRNP* mutation. Most patients with a *PRNP* mutation at codon 102 present with ataxia and have PrP amyloid plaques; such patients are generally given the diagnosis of GSS, but some individuals present with dementia, a clinical characteristic that is usually associated with CJD. For most inherited prion disease, the disease is specified by the respective mutation, such as fCJD(E200K) and GSS(P101L). In the case of FFI, describing the D178N mutation and M129 polymorphism seems unnecessary because this is the only known mutation–polymorphism combination that results in the FFI phenotype. The sporadic form of fatal insomnia is denoted sFI.

5 Discovery of the Prion Protein

The discovery of PrP 27–30 in SHa brain fractions progressively enriched for scrapie infectivity transformed research on scrapie and related diseases. PrP 27–30 was so named because it has an apparent molecular weight (M_r) of 27 kDa to 30 kDa (Fig. 1). PrP 27–30 is derived from the larger PrP^{Sc} by N-terminal truncation; both PrP 27–30 and PrP^{Sc} are infectious. PrP 27–30 not only provided a molecular marker that is specific for prion disorders but it was later shown to be the sole component of the prion particle.

The molecular biology and genetics of prions began with the purification of PrP 27–30 that allowed determination of its N-terminal, amino acid sequence. Multiple signals in each cycle of the Edman degradation suggested that either multiple proteins were present in these ''purified fractions'' or a single protein with a ragged N-terminus was present. When the signals in each cycle were grouped according to their strong, intermediate, and weak intensities, it became clear that a single protein with a ragged N-terminus was being sequenced (Fig. 3). Determination of a single, unique sequence for the N-terminus of PrP 27–30 permitted the synthesis of isocoding mixtures of oligonucleotides that were subsequently used to identify incomplete PrP cDNA clones from hamster and mouse. cDNA clones encoding the entire open reading

Relative amount	Amino acid sequence*
1	G-Q-G-G-G-T-H-N-Q-W-N-K-P-S-K
0.4	X-X-X-T-H-N-X-W-X-K-P

*Single-letter amino acid code. X = amino acid not determined at that cycle.

Fig. 3 Interpreted sequence, shown by single-letter amino acid codes, of the N-terminus of PrP 27–30. The ''ragged ends'' of PrP 27–30 are shown. X = amino acid was not detected at that cycle of the Edman degradation.

frames (ORFs) of SHaPrP and MoPrP were eventually recovered.

6 Prion Protein Isoforms

In Syrian hamsters, PrP^C and PrP^{Sc} are 209-residue proteins that are anchored to the cell surface by a glycosylphosphatidyl inositol (GPI) moiety and have the same covalent structure (Fig. 1). The N-terminal sequencing, the deduced amino acid sequences from PrP cDNA, and immunoblotting studies argue that PrP 27–30 is a truncated protein of approximately 142 residues, which is derived from PrP^{Sc} by limited proteolysis of the N-terminus.

In general, $\sim 10^5$ PrP^{Sc} molecules correspond to one ID_{50} unit (U) using the most sensitive bioassay. PrP^{Sc} is probably best defined as the alternative or abnormal isoform of PrP, which stimulates conversion of PrP^C into nascent PrP^{Sc}, accumulates, and causes disease. Although resistance to limited proteolysis has proved to be a convenient tool for detecting PrP^{Sc}, not all PrP^{Sc} molecules possess protease resistance, as discussed above. Some investigators equate protease resistance with PrP^{Sc} and this erroneous view has been compounded by the use of the term ''PrP-res''.

Although insolubility and protease resistance were used in initial studies to differentiate PrP^{Sc} from PrP^C, subsequent investigations showed that these properties are only surrogate markers of infectivity, as are high β-sheet content and polymerization into amyloid. When these surrogate markers are present, they are useful, but their absence does not establish a lack of prion infectivity. PrP^{Sc} is usually not detected by Western immunoblotting if fewer than 10^5 ID_{50} U mL^{-1} are present in a sample. Furthermore, PrP^{Sc} from different species or prion strains may exhibit different degrees of protease resistance.

6.1 Cell Biology of PrP^{Sc} Formation

In scrapie-infected cells, PrP^C molecules destined to become PrP^{Sc} exit to the cell surface prior to conversion into PrP^{Sc}. Like other GPI-anchored proteins, PrP^C appears to reenter the cell through a subcellular compartment bounded by cholesterol-rich, detergent-insoluble membranes, which might be caveolae or early endosomes. Within this cholesterol-rich, nonacidic compartment, GPI-anchored PrP^C can be either converted into PrP^{Sc} or partially degraded. Subsequently, PrP^{Sc} is trimmed at the N-terminus in an acidic compartment in scrapie-infected cultured cells to form PrP 27–30. In contrast, N-terminal truncation of PrP^{Sc} is minimal in the brain, where little PrP 27–30 is found.

7
Rodent Models of Prion Disease

Mice and hamsters are commonly used in experimental studies of prion disease. The shortest incubation times are achieved with intracerebral inoculation of prions with a sequence identical to that of the host animal; under these conditions, all animals develop prion disease within a narrow interval for a particular dose. When the PrP sequence of the donor prion differs from that of the recipient host, the incubation time is prolonged, and can be quite variable; often, many of the inoculated animals do not develop disease. This phenomenon is generally called the ''species barrier''.

8
PrP Gene Structure and Organization

Prnp is a member of the *Prn* gene family. The second member of this family to be identified is the *Prnd* gene that lies approximately 19 kb downstream from the PrP locus and encodes the doppel (Dpl) protein. The respective genes that encode PrP and Dpl appear to represent ancient gene duplication that occurred an prior to the speciation of mammals. The sequences are approximately 25% identical but the structures of the two proteins are highly conserved (Fig. 4). In contrast to PrP, which is expressed in many different tissues, Dpl expression is confined to the testis. Both Dpl and PrP are found on the surface of sperm but their functions are unknown. In contrast to PrP-deficient ($Prnp^{0/0}$) mice, Dpl-deficient ($Prnd^{0/0}$) mice are sterile. The knockout of both PrP and Dpl genes resulted in a sterile phenotype.

The entire ORF of all known mammalian and avian PrP genes resides within a single exon, which eliminates the possibility that PrP^{Sc} arises from alternative RNA splicing. The two exons of the SHaPrP gene are separated by a 10-kb intron; exon 1 encodes a portion of the 5′ untranslated leader sequence. The PrP

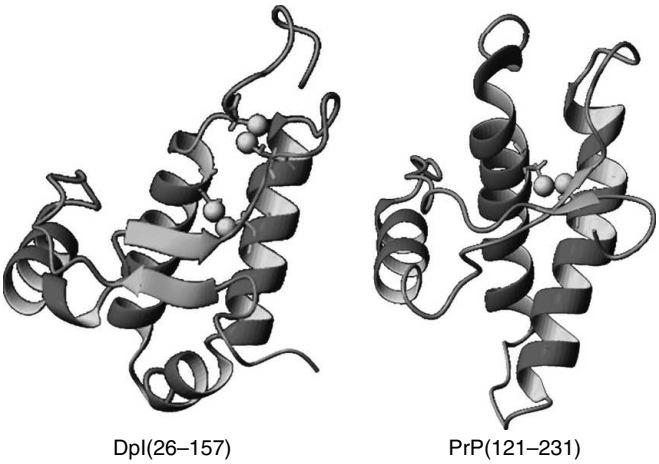

Fig. 4 Comparison of the NMR structures of mouse Dpl and PrP. Backbone topology of mouse Dpl(26–157) and mouse PrP(121–231). Figure prepared by Jane Dyson and Peter Wright.

genes of Syrian hamster, mouse, sheep, and rat contain three exons, with exon 3 encoding the ORF and 3′ untranslated region. The promoters of both the SHaPrP and MoPrP genes contain multiple copies of G-C–rich repeats and are devoid of TATA boxes. These G-C nonamers represent a motif that may function as a canonical binding site for the transcription factor Sp1.

Like the PrP gene, the entire ORF of the Dpl gene is encoded within a single exon. In some lines of *Prnp*$^{0/0}$ mice, high levels of Dpl expression were found in the brain. The expression of Dpl in the CNS was due to intergenic splicing of the nontranslated exons of the PrP gene with the translated exon of Dpl. That Dpl expression is neurotoxic was subsequently demonstrated by construction of Tg mice expressing Dpl in the brain.

8.1 Expression of the PrP Gene

Although PrP mRNA is constitutively expressed in the brains of adult animals, it is highly regulated during development. In the septum, levels of PrP mRNA and choline acetyltransferase were found to increase in parallel during development. In other brain regions, PrP gene expression occurs at an earlier age. *In situ* hybridization studies show that the highest levels of PrP mRNA are found in neurons.

Because no antibodies are currently available that clearly distinguish between PrP^{C} and PrP^{Sc}, PrP^{C} is generally measured in tissues from uninfected control animals, in which no PrP^{Sc} is found. PrP^{Sc} staining was minimal in the regions that intensely stained for PrP^{C}. A similar relationship between PrP^{C} and PrP^{Sc} was found in the amygdala. In contrast, PrP^{Sc} accumulated in the medial habenular nucleus, the medial septal nuclei, and the diagonal band of Broca; these areas were virtually devoid of PrP^{C}. In the white matter, bundles of myelinated axons contained PrP^{Sc} but were devoid of PrP^{C}. These findings suggest that prions are transported along axons, which is consistent with earlier findings in which scrapie infectivity migrated in a pattern consistent with retrograde transport. While the rate of PrP^{Sc} synthesis appears to be a function of the level of PrP^{C} expression in Tg mice, the level of PrP^{Sc} accumulation appears to be independent of PrP^{C} concentration.

8.2 Overexpression of Wild-type PrP Transgenes

Mice expressing different levels of the wild-type (wt) SHaPrP transgene were constructed. Inoculation of these Tg(SHaPrP) mice with SHa prions demonstrated abrogation of the species barrier, resulting in abbreviated incubation times due to a nonstochastic process. The length of the incubation time after inoculation with SHa prions was inversely proportional to the level of $SHaPrP^{C}$ in the brains of Tg(SHaPrP) mice. Bioassays of brain extracts from clinically ill Tg(SHaPrP) mice inoculated with Mo prions revealed that Mo prions, but no SHa prions, were produced. Conversely, inoculation of Tg(SHaPrP) mice with SHa prions led to the synthesis of only SHa prions.

During transgenetic studies, uninoculated older mice harboring high copy numbers of wt PrP transgenes derived from Syrian hamsters, sheep, and *Prnp*^{b} mice spontaneously developed truncal ataxia, hind-limb paralysis, and tremors. These Tg mice exhibited profound necrotizing

myopathy involving skeletal muscle, demyelinating polyneuropathy, and focal vacuolation of the CNS. Development of disease was dependent on transgene dosage. For example, Tg(SHaPrP$^{+/+}$)7 mice homozygous for the SHaPrP transgene array regularly developed disease between 450 and 600 days of age, while hemizygous Tg(SHaPrP$^{+/0}$)7 mice developed disease after >650 days. Attempts to demonstrate spontaneous generation of SHa prions in Tg(SHaPrP$^{+/+}$)7 mice have been unsuccessful.

8.3 PrP Gene Dosage Controls the Incubation Time

Incubation times have been used to isolate prion strains inoculated into sheep, goats, mice, and hamsters. The *Sinc* gene is a major determinant of incubation periods in mice. Once molecular clones of *Prnp* became available, a study was performed to determine if control of the length of the incubation time is genetically linked to the PrP gene. Because the availability of VM mice with prolonged incubation times that were used to define *Sinc* was restricted, I/LnJ mice were used in the crosses. Indeed, the incubation-time locus, designated *Prn-i*, was found to be either congruent with or closely linked to *Prnp*.

Although the amino acid substitutions in PrP that distinguish *Prnp*^{a} from *Prnp*^{b} mice argued for the congruency of *Prnp* and *Prn-i*, experiments with *Prnp*^{a} mice expressing *Prnp*^{b} transgenes demonstrated a ''paradoxical'' shortening of incubation times. These Tg mice were predicted to exhibit a prolongation of the incubation time after inoculation with RML prions based on (*Prnp*^{a} × *Prnp*^{b}) F1 mice, which exhibit long incubation times. Those findings were described as a ''paradoxical'' shortening because we and others had believed for many years that long incubation times are dominant traits. From studies of congenic and transgenic mice expressing different numbers of the *a* and *b* alleles of *Prnp*, these findings were discovered not to be paradoxical; indeed, they resulted from increased PrP gene dosage. When the RML isolate was inoculated into congenic and transgenic mice, increasing the number of copies of the *a* allele was found to be the major determinant in reducing the incubation time; however, increasing the number of copies of the *b* allele also reduced the incubation time, but not to the same extent as that seen with the *a* allele. Gene-targeting studies established that the *Prnp* gene controls the incubation time and as such, is congruent with both *Prn-i* and *Sinc*.

8.4 PrP-deficient Mice

Ablation of the PrP gene in mice did not affect development of these animals. *Prnp*$^{0/0}$ mice remain healthy for more than two years. Acute suppression of PrP expression by addition of doxycycline to the drinking water of bigenic mice with an inducible PrP transgene under the control of the tetracycline promoter did not result in any untoward effects in adult mice. Similarly, bigenic mice, in which neuronal PrP expression was terminated in adulthood, showed no discernable deficits.

In two *Prnp*$^{0/0}$ lines, Purkinje cell loss was accompanied by ataxia beginning at approximately 70 weeks of age. Crossing one of these *Prnp*$^{0/0}$ lines with Tg mice overexpressing MoPrP rescued the ataxic phenotype. With the discovery of Dpl, it became clear, as described above, that Dpl

expression in the brains of these $Prnp^{0/0}$ mice provoked cerebellar degeneration.

$Prnp^{0/0}$ mice inoculated with prions are resistant to infection. $Prnp^{0/0}$ mice were sacrificed 5 days, 60 days, 120 days, and 315 days after inoculation with RML prions and brain extracts were bioassayed in Swiss CD-1 mice. Except for residual infectivity from the inoculum detected at 5 days after inoculation, no infectivity was found in the brain extracts, as the Swiss CD-1 mice did not develop disease.

$Prnp^{0/0}$ mice crossed with Tg(SHaPrP) mice were rendered susceptible to SHa prions but remained resistant to Mo prions. Because the absence of PrP^{C} expression does not provoke disease, it is likely that scrapie and other prion diseases are a consequence of PrP^{Sc} accumulation rather than inhibition of PrP^{C} function. Such an interpretation is consistent with the dominant inheritance of familial prion diseases.

Mice heterozygous ($Prnp^{0/+}$) for ablation of the PrP gene had prolonged incubation times when inoculated with Mo prions and developed signs of neurologic dysfunction at 400 to 460 days after inoculation. These findings are in accord with studies on Tg(SHaPrP) mice in which increased SHaPrP expression was accompanied with shortened incubation times.

Because $Prnp^{0/0}$ mice do not express PrP^{C}, we reasoned that they might more readily produce α-PrP antibodies. $Prnp^{0/0}$ mice immunized with Mo or SHa prion rods produced α-PrP antisera that bound MoPrP, SHaPrP, and HuPrP. These findings contrast with earlier studies in which α-MoPrP antibodies could not be produced in mice presumably because the mice had been rendered tolerant by the presence of $MoPrP^{C}$. That $Prnp^{0/0}$ mice readily produce α-PrP antibodies is consistent with the hypothesis that the lack of an immune response in prion diseases is due to the fact that PrP^{C} and PrP^{Sc} share many epitopes.

8.5 Species Variations in the PrP Sequence

PrP is posttranslationally processed to remove a 22-amino acid, N-terminal signal peptide. The C-terminal 120 amino acids contain two conserved disulfide-bonded cysteines and a sequence that beckons addition of a GPI anchor. Twenty-three residues are removed during the addition of this GPI moiety, which anchors the protein to the cell membrane. Contributing to the mass of the protein are two Asn side chains linked to large oligosaccharides with multiple structures that have been shown to be complex and diverse. Although many species variants of PrP have now been sequenced, only the chicken sequence has been found to differ greatly from the human sequence. The alignment of the translated sequences from more than 40 PrP genes shows a striking degree of conservation between the mammalian sequences and is suggestive of the retention of some important function through evolution (Fig. 5). Cross-species conservation of PrP sequences makes it difficult to draw conclusions about the functional importance of many of the individual residues in the protein.

8.6 N-terminal Sequence Repeats

The N-terminal domain of mammalian PrP contains five copies of a P(H/Q)GGG (G)WGQ octarepeat sequence, occasionally more, as in the case of one sequenced bovine allele, which has six copies. These repeats are remarkably conserved between species, which implies a functionally

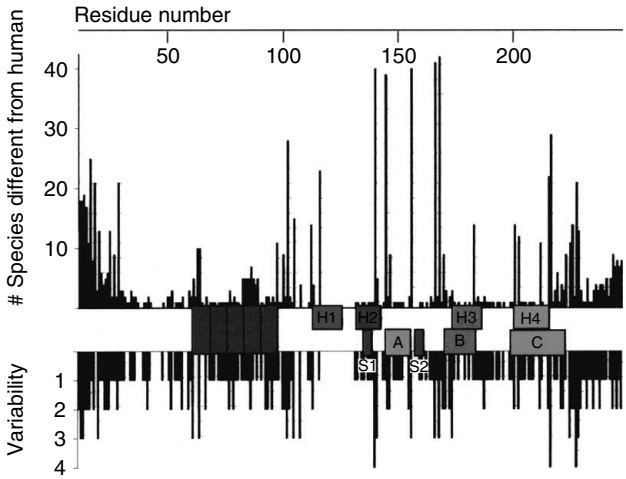

Fig. 5 Species variations and mutations of the prion protein gene. The *x*-axis represents the human PrP sequence, with the five octarepeats and H1–H4 regions of putative secondary structure shown as well as the three α-helices A, B, and C and the two β-strands S1 and S2 as determined by NMR. Vertical bars above the axis indicate the number of species that differ from the human sequence at each position. Below the axis, the length of the bars indicates the number of alternative amino acids at each position in the alignment. Data were compiled by Paul Bamborough and Fred E. Cohen (see color plate p. xxvi).

important role. The chicken sequence contains a different repeat, PGYP(H/Q)N. Although insertions of extra repeats have been found in patients with familial prion disease, naturally occurring deletions of single octarepeats do not appear to cause disease, and deletion of all these repeats does not prevent PrP^{C} from undergoing a conformational transition into PrP^{Sc}.

It was suggested that the histidine residues in the octarepeats might bind metal ions and that immobilized metal ion affinity chromatography (IMAC) might facilitate the purification of PrP; indeed, IMAC did prove to be useful in the purification of PrP^{C}. The availability of purified PrP^{C} allowed studies comparing the secondary structures of PrP^{C} and PrP^{Sc}. The metal ion-peptide complexes were found to be much more soluble than the metal ions bound to full-length PrP. Using full-length recombinant (rec) PrP, Cu^{2+} was found to bind with a much higher avidity than any other metal ion, but the concentration for half-maximal binding for Cu^{2+} was 14 µM at pH 6.0, indicating a rather low affinity of PrP for Cu^{2+}. At neutral pH, Cu^{2+}–PrP complexes tended to form large aggregates and precipitate, so, synthetic peptides containing the octarepeats were used to study more extensively the interaction of Cu^{2+} with PrP. The concentration for half-maximal binding for Cu^{2+} to a peptide (51–75) containing two octarepeats was 6 µM at pH 7.5. When a peptide (58–91) containing four octarepeats was studied, the binding of Cu^{2+} was found to be cooperative and highly pH-dependent (Fig. 6). The midpoint of the pH-dependence transition was pH

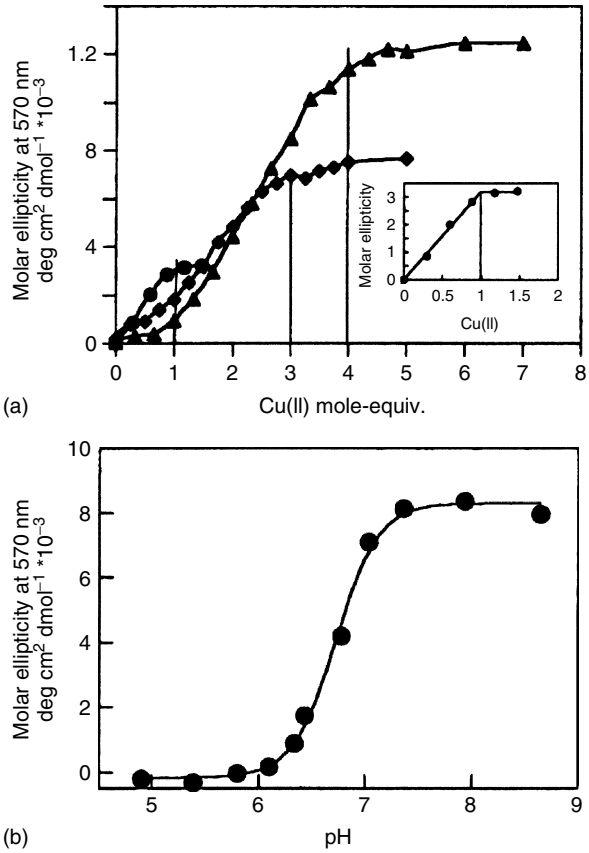

Fig. 6 Binding of copper ions to synthetic peptides containing the octarepeats of PrP. (a) Cu(II) binding curves: molar ellipticity at 570 nm with increasing amounts of Cu(II), pH 7.5. Filled circles, 2-His peptide, PrP(51–75) (0.34 mM). Filled diamonds, 3-His peptide, PrP(66–91) (0.021 mM). Filled triangles, 4-His peptide, PrP(58–91) (0.033 mM). (b) pH dependence of the ellipticity at 570 nm for PrP(58–91). The pH-dependence curve has been fitted to the following equation: $\Delta\varepsilon_{obs} = [\Delta\varepsilon_{acid}[H^+]^n + \Delta\varepsilon_{base}[H^+]K_a]/[H^+]^n + K_a]$, in which n = Hill coefficient and K_a = acid dissolution constant for the transition. The midpoint of the transition is pH 6.7. Reprinted with permission, from (Viles, J.H., Cohen, F.E., Prusiner, S.B., Goodin, D.B., Wright, P.E., Dyson, H.J. (1999) Copper binding to the prion protein: structural implications of four identical cooperative binding sites, *Proc. Natl. Acad. Sci. U. S. A.* **96**, 2042–2047), copyright 1999 National Academy of Sciences, USA.

6.7, suggesting that the binding of Cu^{2+} occurred through the imidazole nitrogens of histidine residues.

In studies of full-length recPrP, Cu^{2+} was found to catalyze the oxidation of the histidine residues within the octarepeats. These findings argue that PrP may function as Cu^{2+}-binding protein. Consistent with studies on recPrP, membranes isolated from the brains of *Prnp*$^{0/0}$ mice were reported to have substantially lower levels of Cu^{2+} than wt mice. However, attempts to confirm this relationship between brain Cu^{2+} and PrP levels were unsuccessful. Interestingly, the copper-chelating reagent cuprizone administered to rodents causes spongiform degeneration resembling that induced by prions.

8.7
Conserved Ala-Gly Region

In addition to the octarepeat, the other region of notable conservation is in the sequence at the C-terminal end of the last octarepeat. Here, an unusual glycine- and alanine-rich region from A113 to Y128 is found (Fig. 5). Although no differences have been found in this part of the sequence between species, a single point mutation A117V is linked to GSS. The conservation of structure suggests an important role in the function of PrP^{C}; in addition, this region is likely to be important in the conversion of PrP^{C} into PrP^{Sc}.

9
Structures of PrP Isoforms

Mass spectrometry and gas phase sequencing were used to search for posttranslational chemical modifications that might explain the differences in the properties of PrP^{C} and PrP^{Sc}. No modifications differentiating PrP^{C} from PrP^{Sc} were found. These observations forced the consideration of the possibility that a conformational change distinguishes the two PrP isoforms.

When the secondary structures of the PrP isoforms were compared by optical spectroscopy, they were found to be markedly different. Fourier transform infrared (FTIR) and circular dichroism (CD) spectroscopy studies showed that PrP^{C} contains approximately 40% α-helix and little β-sheet while PrP^{Sc} is composed of approximately 30% α-helix and 45% β-sheet. That the two PrP isoforms have the same amino acid sequence runs counter to the widely accepted view that the amino acid sequence specifies only one biologically active conformation of a protein. Like PrP^{Sc}, PrP 27–30 has a high β-sheet content, which is consistent with the earlier finding that PrP 27–30 polymerizes into amyloid fibrils. Denaturation of PrP 27–30 under conditions that reduced infectivity resulted in a concomitant diminution of β-sheet content.

Prior to comparative studies on the structures of PrP^{C} and PrP^{Sc}, metabolic labeling studies showed that the acquisition of protease resistance in PrP^{Sc} is a posttranslational process. In a search for chemical differences that would distinguish PrP^{Sc} from PrP^{C}, ethanolamine was identified in hydrolysates of PrP 27–30, which signaled the possibility that PrP might contain a GPI anchor. Both PrP isoforms were found to carry GPI anchors. PrP^{C} was found on the surface of cells, where it could be released by cleavage of the anchor. Subsequent studies showed that PrP^{Sc} formation occurs after PrP^{C} reaches the cell surface and localizes to caveolae-like domains (CLDs).

9.1 NMR Structures of recPrP

The NMR structures of more than 10 PrPs from different species have been determined to be quite similar (Table 4). The recPrP molecules were produced in *E. coli* and isotopically labeled. When refolded into proteins with a high α-helical content, these recPrPs appear to be representative of PrP^{C}. It is noteworthy that recPrPs produced in *E. coli* have neither N-linked sugar chains nor a GPI anchor, both of which are attached to PrP^{C}. However, synthetic prions produced from recMoPrP(89–230) demonstrated that neither N-linked sugar chains nor a GPI anchor is required for PrP^{Sc} formation. The structure of MoDpl

is similar to that of MoPrP even though the two proteins share only 25% sequence similarity (Fig. 4).

The NMR structure of recSHaPrP (90–231) was determined after the protein was purified and refolded (Fig. 7a). Residues 90–112 are not shown because marked conformational heterogeneity was found in this region while residues 113–126 constitute the conserved hydrophobic region that also displays some structural plasticity. Although some features of the structure of recSHaPrP(90–231) are similar to those reported earlier for the smaller recMoPrP(121–231) fragment, substantial differences were found. For example, the loop at the N-terminus of helix B is defined in recSHaPrP(90–231) but is disordered in recMoPrP(121–231); in addition, helix C is composed of residues 200–227 in recSHaPrP(90–231) but extends only from residues 200–217 in recMoPrP(121–231). The loop and the C-terminal portion of

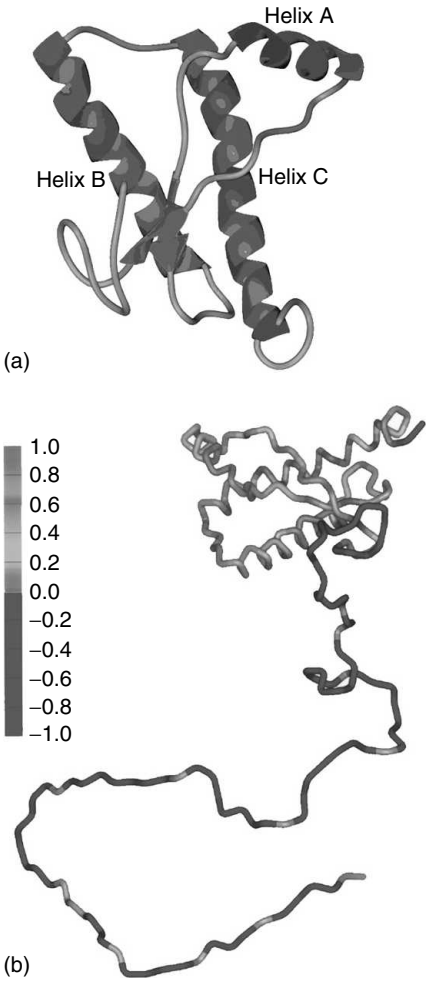

Fig. 7 Structures of PrP^C. (a) NMR structure of Syrian hamster (SHa) recombinant (rec) PrP(90–231). Presumably, the structure of the α-helical form of recPrP(90–231) resembles that of PrP^C. recPrP(90–231) is viewed from the interface where PrP^{Sc} is thought to bind to PrP^C. The color scheme is: α-helices A (residues 144–157), B (172–193), and C (200–227) in blue; loops in yellow; residues 129–134 encompassing strand S1 and residues 159–165 encompassing strand S2 in green. (b) Schematic diagram showing the flexibility of the polypeptide chain for PrP(29–231). The structure of the portion of the protein representing residues 90–231 was taken from the coordinates of PrP(90–231). The remainder of the sequence was hand-built for illustration purposes only. The color scale corresponds to the heteronuclear $[^1H]$-^{15}N NOE data: red for the lowest (most negative) values, where the polypeptide is most flexible, to blue for the highest (most positive) values in the most structured and rigid regions of the protein. (See color plate. p. xxviii)

helix C are particularly important, as described below. Whether the differences between the two recPrP fragments are due to (1) their different lengths, (2) species-specific differences in sequences, or (3) the conditions used for solving the structures remains to be determined.

NMR studies of recMoPrP(23–231) and recSHaPrP(29–231) showed that like the shorter fragments described above, full-length PrP is also a three helix–bundle protein with two short antiparallel β-strands. While the three helices form a globular C-terminal domain, the N-terminal domain is highly flexible and lacks identifiable secondary structure under the experimental conditions employed (Fig. 7b). Studies of recSHaPrP(29–231) indicate transient interactions between the C-terminal end of helix B and the highly flexible, N-terminal random-coil containing the octarepeats (residues 29–125).

9.2 Electron Crystallography of PrP^{Sc}

Because the insolubility of PrP^{Sc} has frustrated structural studies by X-ray crystallography or NMR spectroscopy, electron crystallography was used to characterize the structure of two infectious variants of PrP. Isomorphous, two-dimensional crystals of PrP 27–30 and a miniprion (PrP^{Sc}106) were identified by negative-stain electron microscopy. Image processing allowed the extraction of limited structural information to 7-Å resolution. Comparing projection maps of PrP 27–30 and PrP^{Sc}106, the 36-residue internal deletion of the miniprion was visualized and the N-linked sugars were localized (Fig. 8). The dimensions of the monomer and the locations of the deleted segment and sugars were used as constraints in the construction of models for PrP^{Sc}. Only models featuring parallel β-helices as the key element could satisfy the constraints.

A single antiparallel β-sheet as previously suggested was not consistent with the observed densities in the projection maps obtained from the 2D crystals. Specifically, the sheets were far too wide to fit into the observed hexameric arrangement. Efforts to adjust the sheet morphology to fit the density required the use of shorter strands. The amount of β-structure in these altered β-sheets was no longer compatible with the amounts of β-sheet observed by FTIR spectroscopy. Furthermore, antiparallel β-sheets typically have a twist of $\sim 20^\circ$ per strand.

From a study of 119 all-β folds observed in globular proteins, it was determined that if PrP^{Sc} follows a known protein fold, it adopts either a β-sandwich or parallel β-helical architecture. With increasing evidence arguing for a parallel β-sheet organization in amyloids, it was argued that the sequence of PrP is compatible with a parallel left-handed β-helical fold. Left-handed β-helices readily form trimers, providing a natural template for a trimeric model of PrP^{Sc} (Fig. 9a). This trimeric model accommodates the PrP sequence from residues 89–175 in a β-helical conformation with the C-terminus (residues 176–227) retaining the disulfide-linked α-helical conformation observed in PrP^{C}. In addition, the proposed model matches the structural constraints of the crystals, positioning residues 141–176 and the N-linked sugars appropriately. The parallel left-handed β-helical model provides a coherent framework that is consistent with the stacking of trimeric units of PrP 27–30 to form PrP amyloid fibrils (Fig. 9b).

10 Prion Replication

The mechanism of prion replication is not well understood. The formation of nascent prions requires that PrP^C be converted into PrP^{Sc}. Some investigators have argued that this process involves a nucleation–polymerization (NP) reaction while others have contended that a more likely mechanism employs a template-assisted process.

In an uninfected cell, PrP^C with the wt sequence is likely to exist in equilibrium in its monomeric α-helical, protease-sensitive state or bound to some other protein, such as protein X (Fig. 10). The conformation of PrP^C that is bound to protein X is denoted PrP*; this conformation is likely to be different from that determined under aqueous conditions for monomeric recPrP. The PrP*–protein X complex will bind PrP^{Sc}, thereby creating a replication-competent assembly. Order-of-addition experiments demonstrate that protein X binding to PrP^C precedes productive PrP^{Sc} interactions. A conformational change takes place wherein PrP*, in a shape competent for binding to protein X and PrP^{Sc}, represents the initial phase in the formation of infectious PrP^{Sc}.

Although many lines of evidence reviewed below argue for a template-assisted process in the formation of nascent PrP^{Sc}

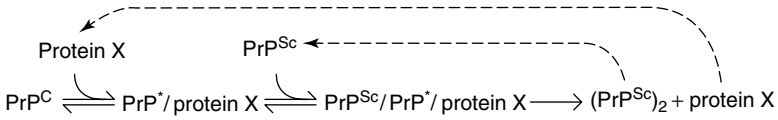

Fig. 10 Hypothetical scheme for template-assisted PrP^{Sc} formation. In the initial step, PrP^C binds to protein X to form the PrP*–protein X complex. Next, PrP^{Sc} binds to PrP* that has already formed a complex with protein X. When PrP* is transformed into a nascent molecule of PrP^{Sc}, protein X is released and a dimer of PrP^{Sc} remains. The inactivation target size of an infectious prion suggests that it is composed of a dimer of PrP^{Sc}. In the model depicted here, a fraction of infectious PrP^{Sc} dimers dissociates into uninfectious monomers as the replication cycle proceeds, while a majority of the dimers accumulates in accord with the increase in prion titer that occurs during the incubation period. Another fraction of PrP^{Sc} is cleared presumably by cellular proteases. The precise stoichiometry of the replication process remains uncertain. Reprinted with permission, from (Prusiner, S.B., Scott, M.R., DeArmond, S.J., Cohen, F.E. (1998) Prion protein biology, *Cell* **93**, 337–348), copyright 1998 Cell Press.

in mammalian cells, the formation of synthetic prions from PrP(89–143,P101L) as well as from recPrP(89–230) establishes that infectious prions can be generated *de novo* without the aid of auxiliary proteins.

10.1 Mechanism of Prion Propagation

In attempting to probe the mechanism of prion formation, it is reasonable to determine the rate-limiting step in prion formation. First, the impact of the concentration of PrP^{Sc} in the inoculum, which is inversely proportional to the length of the incubation time, must be considered. Second, the sequence of PrP^{Sc} that forms an interface with PrP^{C} must be taken into account. When the sequences of the two isoforms are identical, the shortest incubation times are observed. Third, the strain-specific conformation of PrP^{Sc} must be considered. Some prion strains exhibit longer incubation times than others; the mechanism underlying this phenomenon is not understood. From these considerations, a set of conditions exist under which initial PrP^{Sc} concentrations can be rate limiting. These effects presumably relate to the stability of the PrP^{Sc}, its targeting to the correct cells and subcellular compartments, and its ability to be cleared. Once infection in a cell is initiated and endogenous PrP^{Sc} production is operative, then the following discussion of PrP^{Sc} formation seems most applicable. If the assembly of PrP^{Sc} into a specific dimeric or multimeric arrangement is difficult, then an NP formalism would be relevant. In NP processes, nucleation is the rate-limiting step and elongation, or polymerization, is facile. These conditions are frequently observed in peptide models of aggregation phenomena; however, studies in ScN2a cells and with Tg mice expressing foreign PrP genes suggest that a different process occurs.

10.2 Template-assisted Prion Formation

From investigations with mice expressing both the SHaPrP transgene and the endogenous MoPrP gene, designated Tg(SHaPrP) mice, it is clear that PrP^{Sc} provides a template for directing prion replication; a template is defined as a catalyst that leaves its imprint on the product of the reaction. Inoculation of these mice with $SHaPrP^{Sc}$ leads to the production of nascent $SHaPrP^{Sc}$ and not $MoPrP^{Sc}$. Conversely, inoculation of the Tg(SHaPrP) mice with $MoPrP^{Sc}$ results in $MoPrP^{Sc}$ and not $SHaPrP^{Sc}$ formation.

Even stronger evidence for templating has emerged from studies of prion strains passaged in Tg(MHu2M)$Prnp^{0/0}$ mice, which express a chimeric mouse–human gene, as described in more detail below. Even though the conformational templates were initially generated with PrP^{Sc} molecules having different sequences from patients with inherited prion diseases, these templates are sufficient to direct replication of distinct PrP^{Sc} molecules when the amino acid sequences of the substrate PrPs are identical.

Another line of evidence for template-assisted prion replication comes from studies of FI. In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has an M_r of 19 kDa when measured by immunoblotting of brain extracts from humans with FFI or from Tg(MHu2M)$Prnp^{0/0}$ mice that were inoculated with FFI prions. In both humans and inoculated Tg(MHu2M)$Prnp^{0/0}$ mice on both first and second passage, PrP^{Sc} is confined largely to the thalamus. These findings argue that the conformation of

PrP^{Sc} that yields a 19-kDa polypeptide after deglycosylation is propagated both in humans and in mice expressing an artificial chimeric transgene; in addition, prion accumulation is confined to the thalamus. Additional evidence supporting these assertions comes from a patient who died after developing a clinical disease similar to FFI. Because both PrP alleles encoded the wt PrP sequence and methionine at position 129, we labeled this sFI. At autopsy, the spongiform degeneration, reactive astrocytic gliosis, and PrP^{Sc} deposition were confined to the thalamus. Moreover, the PrP^{Sc} both in the patient's brain and in the brains of inoculated Tg(MHu2M)*Prnp*$^{0/0}$ mice yielded a 19-kDa fragment after deglycosylation. These findings argue that the clinicopathologic phenotype is determined by the conformation and not the amino acid sequence of PrP^{Sc}. Additionally, FI prions can be replicated with mutant human PrP(D178N), wt human PrP, or chimeric human–mouse PrP. With these different PrPs as substrates, the conformation of PrP^{Sc} must be faithfully copied; template-assisted prion replication provides for such a mechanism.

10.3 Evidence for Protein X

Protein X was postulated to explain the results of the transmission of Hu prions to Tg mice (Table 5). Mice expressing both $MoPrP^{C}$ and $HuPrP^{C}$ were resistant while those expressing only $HuPrP^{C}$ were susceptible to Hu prions. These results argue that $MoPrP^{C}$ inhibited transmission of Hu prions, that is, the formation of nascent $HuPrP^{Sc}$. In contrast, mice expressing both $MoPrP^{C}$ and chimeric $MHu2MPrP^{C}$ were susceptible to Hu prions and mice expressing $MHu2MPrP^{C}$ alone were only slightly more susceptible. These findings contend that $MoPrP^{C}$ has only a minimal effect on the formation of chimeric $MHu2MPrP^{Sc}$.

When the data on Hu prion transmission to Tg mice were considered together, they suggested that $MoPrP^{C}$ prevented the conversion of $HuPrP^{C}$ into PrP^{Sc} by binding to another Mo protein (protein X) with a higher affinity than $HuPrP^{C}$ does. It was postulated that $MoPrP^{C}$ has little effect on the formation of PrP^{Sc} from $MHu2MPrP^{C}$ (Table 5) because $MoPrP^{C}$ and $MHu2MPrP^{C}$ share the same amino

Tab. 5 Influence of prion species and strain on transmission to Syrian hamsters and mice[a].

Inoculum	*Recipient*	*Incubation time [days ± SEM] (n/n_0)*	
		Sc237 prions	*139H prions*
SHa>SHa	SHa	77 ± 1 (48/48)	167 ± 1 (94/94)
SHa>SHa	non-Tg mice	>700 (0/9)	499 ± 15 (11/11)
SHa>SHa	Tg(SHaPrP)81 mice	75 ± 2 (22/22)	110 ± 2 (19/19)

[a]The species of prion is encoded by the primary structure of PrP^{Sc} and the strain of prion is enciphered by the tertiary structure of PrP^{Sc}. We recognize that the primary structure as well as posttranslational chemical modifications determine the tertiary structure of PrP^{C}, but we argue that the conformation of PrP^{C} is modified by PrP^{Sc} as it is refolded into a nascent PrP^{Sc} molecule.

acid sequence at the C-terminus. This also suggested that MoPrP^{C} only weakly inhibited transmission of SHa prions to Tg(SHaPrP) mice because SHaPrP is more closely related to MoPrP than to HuPrP.

The search for protein X has been frustrating because many proteins are known to bind to PrP^{C} but none have been shown to participate in PrP^{Sc} formation. Whether protein X is one protein or a complex of proteins remains to be established. It is reasonable to expect that mice deficient in protein X would not replicate prions or do so extremely slowly, resulting in prolonged incubation times.

10.4 Dominant-negative Inhibition

To extend the foregoing findings in Tg mice, an expression vector with an insert encoding a chimeric mouse–hamster PrP, designated MHM2PrP, was transfected into ScN2a cells. MHM2PrP carries two Syrian hamster residues, which create an epitope that is recognized by the anti-SHaPrP 3F4 mAb that does not react with mouse PrP. Substitution of a Hu residue at position 214 or 218 in MHM2PrP prevented formation of MHM2PrP^{Sc} in ScN2a cells. The side chains of these residues protrude from the same surface of the C-terminal α-helix, forming a discontinuous epitope with residues 167 and 171 in an adjacent loop. Like MHM2PrP(Q218K), substitution of a basic residue at position 167 or 171 prevented PrP^{Sc} formation. When MHM2PrP and MHM2PrP(Q218K) were coexpressed, the conversion of MHM2PrP^{C} into PrP^{Sc} was inhibited, arguing that MHM2PrP(Q218K) was acting as a dominant negative. Similar results were obtained when studies were performed with cells expressing MHM2PrP(Q167R).

One interpretation of dominant-negative inhibition of prion propagation is that mutant PrP binds more avidly to protein X than does wt PrP. In this scenario, mutant PrP binds to protein X and prevents binding of wt PrP. This explanation is also consistent with the protective effects of basic polymorphic residues in PrP of humans and sheep. The E219K substitution seems to render humans resistant to sCJD and Q171R renders sheep resistant to scrapie. In MHM2, the Q218K mutation corresponds to E219K in humans and the Q167R mutation corresponds to Q171R in sheep (Fig. 11).

To determine whether dominant-negative inhibition of prion formation occurs *in vivo*, Tg mice expressing PrP with either the Q167R or Q218K substitution alone or in combination with wt PrP were produced. Tg(MoPrP,Q167R) *Prnp*$^{0/0}$ mice expressing mutant PrP at levels equal to non-Tg FVB mice were inoculated with prions and remained healthy for more than 550 days, indicating that inoculation did not initiate a process sufficient to cause disease. Immunoblots of brain homogenates and histologic analysis revealed no abnormalities. Tg(MoPrP,Q167R) *Prnp*$^{+/+}$ mice expressing both mutant and wt PrP exhibited neurologic dysfunction at ~450 days after inoculation; the brains of three of these mice that were sacrificed at 300 days revealed low levels of PrP^{Sc} as well as numerous vacuoles and severe astrocytic gliosis. Both Tg(MoPrP,Q218K) *Prnp*$^{0/0}$ and Tg(MoPrP,Q218K) *Prnp*$^{+/+}$ mice expressing the transgene product at 16× remained healthy for more than ~450 days after inoculation. Neither PrP^{Sc} deposition nor neuropathology was found. Tg mice expressing MoPrP(Q218K) at 32× developed spontaneous neurodegeneration at ~450 days of age. These studies

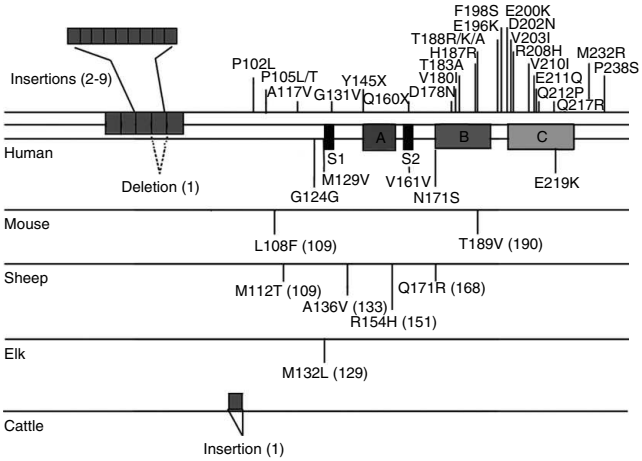

Fig. 11 Mutations and polymorphisms of the prion protein gene. PrP mutations causing inherited human prion disease and PrP polymorphisms found in humans, mice, sheep, elk, and cattle. Above the line of the human sequence are mutations that cause inherited prion disease. Below the lines are polymorphisms, some but not all of which are known to influence the onset as well as the phenotype of disease. Residue numbers in parentheses correspond to the human codons. Much of the data was compiled by J.-L. Laplanche.

demonstrate that although dominant-negative inhibition of wt PrP^{Sc} formation occurs, expression of dominant-negative PrP at the same level as wt PrP does not completely prevent prion formation. However, expression of dominant-negative PrP alone had no deleterious effects on the mice and did not support prion propagation.

11 Sporadic Human Prion Diseases

In most patients with CJD, there is neither an infectious nor heritable etiology. How prions arise in patients with sCJD is unknown; hypotheses include: (1) horizontal transmission from humans or animals; (2) somatic mutation of the *PRNP* ORF; (3) spontaneous conversion of PrP^{C} into PrP^{Sc}; and (4) the accumulation of PrP^{Sc}, which is normally present at very low levels. Numerous attempts to establish an infectious link between sCJD and a preexisting prion disease in animals or humans have been unrewarding. Studies demonstrating the formation of synthetic prions from PrP(89–143,P101L) as well as from recPrP(89–230) show that only PrP^{C} is needed for an animal for producing infectious prions. Thus, the spontaneous conversion of PrP^{C} to PrP^{Sc} seems reasonable and any mammal expressing PrP^{C} is capable of forming prions.

12 Heritable Human Prion Diseases

The recognition that 10 to 15% of CJD cases are familial led to the suspicion that genetics plays a role in this disease. As with scrapie, the relative contributions of genetic and infectious etiologies in the human prion diseases remain puzzling.

More than 30 different mutations of the PrP gene have been shown to segregate with the heritable human prion diseases. Five of these mutations have been genetically linked to the inherited human prion diseases (Table 3). Virtually all cases of GSS and FFI appear to be caused by germline mutations in the PrP gene. The brains of humans dying of inherited prion disease contain infectious prions that have been transmitted to experimental animals.

12.1 GSS and Genetic Linkage

The discovery that GSS, which is a familial disease, could be transmitted to apes and monkeys was first reported when many still thought that scrapie, CJD, and related disorders were caused by viruses. With the discovery that the P102L mutation of the human PrP gene was genetically linked to GSS, prion diseases were concluded to have both genetic and infectious etiologies. In that study, the P102L mutation was linked to development of GSS with a logarithm of the odds (LOD) score exceeding 3, demonstrating a tight association between the altered genotype and disease phenotype (Fig. 3B). This mutation may be caused by the deamination of a methylated CpG in a germline PrP gene, which results in the substitution of a leucine for proline. This mutation has been found in many families in numerous countries, including the first family identified to have GSS.

12.2 fCJD Caused by Octarepeat Inserts

An insert of 144 bp containing six octarepeats at codon 53, in addition to the five that are normally present, was described in patients with CJD from four families residing in southern England. Genealogic investigations showed that all four families are related, arguing for a single founder born more than two centuries ago. The LOD score for this extended pedigree exceeds 11. Studies from several laboratories have demonstrated that inserts of two, four, five, six, seven, eight, or nine octarepeats in addition to the normal five are found in individuals with inherited CJD (Fig. 11).

12.3 fCJD in Libyan Jews

The unusually high incidence of CJD among Israeli Jews of Libyan origin was thought to be due to the consumption of lightly cooked sheep brain or eyeballs. Molecular genetic investigations revealed that Libyan and Tunisian Jews with fCJD have a PrP gene point mutation at codon 200, resulting in a Glu-to-Lys substitution (Fig. 11). The E200K mutation has been genetically linked to fCJD, with an LOD score exceeding 3; the same mutation has also been found in patients from Orava in North Central Slovakia, in a cluster of familial cases in Chile, and in a large German family living in the United States.

Most patients are heterozygous for the mutation and thus, express both mutant and wt PrP^{C}. In the brains of patients who die of fCJD(E200K), mutant PrP^{Sc} is both insoluble and protease-resistant, whereas much of wt PrP differs from both PrP^{C} and PrP^{Sc} in that it is insoluble but readily digested by proteases. Whether this form of PrP is an intermediate in the conversion of PrP^{C} into PrP^{Sc} remains to be established.

12.4 Penetrance of fCJD

Life-table analyses of carriers harboring the codon 200 mutation exhibit complete

penetrance. Therefore, if the carriers live long enough, they will all eventually develop prion disease. Some investigators have argued that the inherited prion diseases are not fully penetrant and thus an environmental factor, such as the ubiquitous "scrapie virus," is required for illness to be manifest, but no viral pathogen has been found to date.

12.5 Fatal Familial Insomnia

The D178N mutation has been linked to the development of FFI, with an LOD score exceeding 5. More than 30 families worldwide with FFI have been recorded. Studies of inherited human prion diseases demonstrate that the amino acid at polymorphic residue 129 with the D178N pathogenic mutation alters the clinical and neuropathologic phenotype. The D178N mutation combined with M129 results in FFI. In this disease, adults generally over age 50 years present with a progressive sleep disorder and usually die within one year. In their brains, deposition of PrP^{Sc} is confined largely within the anteroventral and the dorsal medial nuclei of the thalamus. In contrast, the same D178N mutation with V129 produces fCJD, in which the patients present with dementia and widespread deposition of PrP^{Sc} is found postmortem. The first family to be recognized with CJD was found to carry the D178N mutation.

12.6 Human PrP Gene Polymorphisms

Several polymorphisms in the PrP gene may affect the development and expression of prion disease. A Met/Val polymorphism at PrP codon 129 has been identified (Fig. 11). This polymorphism appears to influence expression of the inherited as well as the iatrogenic and sporadic forms of prion disease. A second polymorphism resulting in an amino acid substitution at codon 219 (Glu/Lys) has been reported to occur with a frequency of approximately 12% in the Japanese population but not in Caucasians. In people heterozygous for the lysine substitution, this expression seems to act as a dominant negative and protects against CJD by the avid binding of mutant PrP^{C} to protein X. By sequestering protein X, PrP^{C}(K219) prevents PrP^{C}(E219) from being converted into PrP^{Sc}. In people homozygous for the lysine substitution, it seems likely that PrP^{C}(K219) is not converted into PrP^{Sc}. A third polymorphism results in an amino acid substitution at codon 171 (Asn/Ser), which lies adjacent to the protein X binding site. This polymorphism has been found in Caucasians but it has not been studied extensively and it is not known to influence the binding of PrP^{C} to protein X. A fourth polymorphism is the deletion of a single octarepeat (24 bp), which has been found in 2.5% of Caucasians. In another study of over 700 individuals, this single octarepeat deletion was found in 1.0% of the population.

Studies of Caucasian patients with sCJD have shown that most are homozygous for Met or Val at codon 129. This contrasts with the general Caucasian population, in which frequencies for the codon 129 polymorphism are 12% Val/Val, 37% Met/Met, and 51% Met/Val. In contrast, the frequency of the valine allele in the Japanese population is much lower. Heterozygosity at codon 129 is more frequent in Japanese CJD patients (18%) than in the general Japanese population, in which the polymorphism frequencies are 0% Val/Val, 92% Met/Met, and 8% Met/Val.

While no specific mutations have been identified in the PrP gene of patients with sCJD, homozygosity at codon 129 is consistent with the results of Tg mouse studies. The finding that homozygosity at codon 129 predisposes to sCJD supports a model of prion production that favors PrP interactions between homologous proteins, as appears to occur in Tg(SHaPrP) mice inoculated with either hamster prions or mouse prions, as well as in Tg(MHM2) mice inoculated with ''artificial'' prions.

13
Infectious Human Prion Diseases

Prions from different sources have infected humans. Human prions have been transmitted to others both by ritualistic cannibalism and iatrogenic means. Kuru in the highlands of New Guinea was transmitted by ritualistic cannibalism, as people in the region attempted to immortalize their dead relatives by eating their brains. Iatrogenic transmissions include prion-tainted human growth hormone (HGH) and gonadotropin, dura mater grafts, and corneal transplants from people who died of CJD. In addition, CJD cases have been recorded after neurosurgical procedures in which ineffectively sterilized depth electrodes or instruments were used.

13.1
Human Growth Hormone

More than 165 young adults have been diagnosed with iatrogenic (i) CJD between 4 and 30 years after receiving HGH or gonadotropin from cadaveric pituitaries. The longest incubation periods (20 to 30 years) are similar to those associated with more recent cases of kuru. Since 1985, recombinant HGH produced in *E. coli* has been used in place of cadaveric HGH. With recombinant HGH, no cases of iCJD have been identified.

13.2
Variant Creutzfeldt–Jakob Disease (vCJD)

In 1994, the first cases of CJD in teenagers and young adults that were eventually labeled variant (v) CJD occurred in Great Britain. More than 150 teenagers and young adults have died of vCJD in Britain, Ireland, Italy, and France. While the average age of vCJD patients is 26 years of age, the youngest patient was 12 years old and the oldest was 74 years of age. The median duration of illness was 13 months, with the range from 6 to 69 months.

In addition to the young age of these patients, vCJD is characterized by numerous PrP amyloid plaques surrounded by a halo of intense spongiform degeneration in the brain. These unusual neuropathologic changes have not been seen in CJD cases in the United States, Australia, or Japan. Both macaque monkeys and marmosets developed neurologic disease several years after inoculation with bovine prions, but only the macaques exhibited numerous PrP plaques similar to those found in vCJD.

The majority of vCJD patients presented with psychiatric symptoms, including dysphoria, withdrawal, anxiety, insomnia, and loss of interest. Generally, neurologic deficits did not appear until at least four months later; these neurologic changes consisted of memory loss, paresthesias, sensory deficits, gait disturbances, and dysarthria. To date, all vCJD cases have been reported from Britain, except for six cases in France, one in Italy, one in Ireland, and one in the United States. The US case is a 23-year-old woman, who is thought to have been exposed to bovine prions while living in Britain during the first 12 years of

her life. From both epidemiologic and experimental studies, evidence is now quite compelling that vCJD is the result of prions being transmitted from cattle with BSE to humans through consumption of contaminated beef products.

Studies of the prion diseases have taken on new significance with the identification of vCJD. The number of cases of vCJD caused by bovine prions that will occur in the years ahead is unknown. Until more time passes, it will be impossible to assess the magnitude of this problem. These tragic cases have generated a continuing discourse concerning mad cows, prions, and the safety of the human and animal food supplies throughout the world. Untangling politics and economics from the science of prions seems to have been difficult in disputes between Great Britain and other European countries over the safety of beef and lamb products.

13.3 Transmission of vCJD Prions by Blood Transfusion

vCJD has been identified in two patients who received blood transfusions from donors that later died of vCJD. In one case, the recipient was a 69-year-old male who was transfused 6.5 years before the onset of neurologic dysfunction. His PrP gene encoded Met/Met at position 129. Many details of the second case are not published but the patient is known to have died of a non-neurologic disease. While vCJD prions were found in the spleen and cervical lymph nodes of this patient, none were found in the brain. The patient's PrP gene encoded Met/Val at position 129 and as such, is the first heterozygous codon 129 human identified with vCJD prions.

A glimpse of future vCJD cases caused by prion-tainted transfused blood may come from a survey of tissues collected during appendectomies and tonsillectomies. This UK survey reports that of the 12 674 appendectomy specimens examined, three were positive for PrP^{Sc} by immunohistochemistry. This finding argues that as many as 3800 people in the United Kingdom may be replicating vCJD prions in their lymphoid tissues. Considering that immunohistochemistry is less sensitive than Western immunoblotting, the number of people with vCJD prions in their lymphoid tissues may be substantially greater than the above estimate.

14 Strains of Prions

That goats with scrapie can manifest two different syndromes, one in which the goats became hyperactive and the other in which they became drowsy, raised the possibility that strains of prions might exist. Subsequent studies with mice documented the existence of multiple strains through careful measurements of incubation times and the distribution of vacuoles in the CNS.

The search for an explanation of how biological information encrypting the disease phenotype could be enciphered within the prion posed a conundrum. Many investigators kept arguing for a small nucleic acid but none could be found. Others argued that this information must be enciphered within the structure of PrP^{Sc}. The first evidence supporting the hypothesis that strain-specific information is enciphered in PrP^{Sc} came from studies on prions causing TME, which were passaged into Syrian hamsters. On serial passaging, two strains

emerged: one strain (HY) produced hyperactivity in Syrian hamsters and the other (DY) was manifest as a drowsy syndrome, as was seen with scrapie strains in goats. The HY strain was similar to the Sc237 prion strain with respect to protease resistance and sedimentation properties, while the DY strain showed minimal protease resistance and was less readily sedimented.

Because the HY and DY strains emerged after passaging TME prions in Syrian hamsters, concern over the origin of these strains made the conclusions somewhat questionable. Because of such concerns, a more convincing investigation came from the transmission of FFI and fCJD to Tg mice. In this study, two different strains of prions were generated *de novo* in patients with PrP gene mutations and propagated in mice expressing the chimeric MHu2MPrP transgene. Brain homogenates of FFI and fCJD(E200K) patients transmitted disease to Tg(MHu2M) mice approximately 200 days after inoculation. The FFI inoculum induced formation of a 19-kDa PrP^{Sc} fragment, as measured by SDS-PAGE after limited proteolysis and removal of Asn-linked carbohydrates; in contrast, fCJD(E200K) produced a 21-kDa PrP^{Sc} fragment. On second passage, Tg(MHu2M) mice inoculated with FFI prions showed an incubation time of ~130 days and a 19-kDa PrP^{Sc} fragment while those inoculated with fCJD(E200K) prions exhibited an incubation time of ~170 days and a 21-kDa PrP^{Sc} fragment. The experimental data demonstrated that MHu2MPrP^{Sc} can exist in two different conformations, based on the sizes of the protease-resistant fragments, within an invariant amino acid sequence. The results of these studies argue that PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}. Imparting the size of the protease-resistant fragment of PrP^{Sc} through conformational templating provides a mechanism for both the generation and propagation of prion strains.

In another set of studies, prions from cattle with BSE and humans with vCJD were used to demonstrate distinct prion strains in humans expressing wt PrP, in contrast to the studies described above with prions from patients harboring the E200K mutation. Both BSE and vCJD prions transmitted to Tg mice expressing BoPrP but not to mice expressing either HuPrP or MHu2MPrP. Moreover, sCJD, iCJD, and fCJD(E200K) prions failed to transmit disease to Tg(BoPrP) mice after more than 500 days. These findings demonstrate the prions that cause BSE and vCJD are similar, but distinct from those responsible for sCJD, iCJD, and fCJD(E200K).

14.1 Isolation of New Strains

Additional evidence implicating PrP in the phenomenon of prion strains comes from studies on the interspecies transmission of strains. Such studies were especially revealing when mice expressing chimeric hamster–mouse transgenes were used. Evidence was obtained showing that new strains pathogenic to Syrian hamsters could be obtained from prion strains that had been previously replicated by limiting dilution in mice. Both the generation and propagation of prion strains result from interactions between PrP^{Sc} and PrP^{C}. Additionally, strains that were isolated from different breeds of sheep with scrapie and thought to be distinct were shown to have identical properties. Such findings argue for the convergence of some strains and raise the issue of the limits of prion diversity.

Studies with different strains of prions propagated in Syrian hamsters and subsequently in Tg mice expressing MH2MPrP are most illustrative with respect to the isolation of new prion strains. These Tg mice were inoculated with the two prion strains, Sc237 and DY that had been serially passaged in Syrian hamsters. On first passage in Tg(MHM2)$Prnp^{0/0}$ mice, the SHa(Sc237) prions exhibited prolonged incubation times, typical of a species barrier. On subsequent passage in Tg(MHM2)$Prnp^{0/0}$ mice, the MH2M(Sc237) strain showed a profound shortening of incubation time. Moreover, PrP^{Sc} of the MH2M(Sc237) strain possesses different structural properties from PrP^{Sc} of the SHa(Sc237) strain, as demonstrated by relative conformational stability measurements. Conversely, transmission of SHa(DY) prions to Tg(MHM2)$Prnp^{0/0}$ mice did not encounter a species barrier and the MH2M(DY) strain retained the conformational and phenotypic properties of SHa(DY). These results extend the findings described above for FFI and fCJD(E200K) prions and contend that a change in PrP^{Sc} conformation is intimately associated with the emergence of a new prion strain.

14.2 Interplay between the Species and Strains of Prions

The recent advances in our understanding of the role of the primary and tertiary structures of PrP in the transmission of disease have given new insights into the pathogenesis of the prion diseases. The amino acid sequence of PrP encodes the species of the prion (Table 5), and the prion derives its PrP^{Sc} sequence from the last mammal in which it was passaged. While the primary structure of PrP is likely to be the most important or even sole determinant of the tertiary structure of PrP^{C}, existing PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^{C}. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc} and prion strains represent different conformers of PrP^{Sc}. The total number of prion strains, that is, different conformations of PrP^{Sc}, in existence remains to be established.

15 Prion Diseases of Animals

The prion diseases of animals include scrapie of sheep and goats, BSE, TME, chronic wasting disease (CWD) of mule deer and elk, feline spongiform encephalopathy, and exotic ungulate encephalopathy (Table 1).

15.1 PrP Polymorphisms in Sheep, Cattle, and Elk

In 1962, Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease that could be eradicated by proper breeding protocols. He considered its transmission by inoculation of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease and argued that host genetics only modulates susceptibility to an endemic infectious agent.

In sheep, polymorphisms at codons 136, 154, and 171 of the PrP gene that produce amino acid substitutions have been studied with respect to the

incidence of scrapie (Fig. 11). Studies of natural scrapie in the United States have shown that 85% of afflicted sheep are of the Suffolk breed. Only those Suffolk sheep homozygous for Gln (Q) at codon 171 developed scrapie although healthy controls with Gln/Gln, Gln/Arg, and Arg/Arg genotypes were also found. These results argue that susceptibility in Suffolk sheep is governed by the PrP codon 171 polymorphism. As with the Suffolk breed, the PrP codon 171 polymorphism in Cheviot sheep has a profound influence on susceptibility to scrapie, and codon 136 also modulates susceptibility but less so than codon 171.

In contrast to sheep, different breeds of cattle have no specific PrP polymorphisms. The only polymorphism recorded in cattle is a variation in the number of octarepeats: most cattle, like humans, have five octarepeats but some have six. However, the presence of six octarepeats does not seem to be overrepresented in BSE.

In studies of CWD, the susceptibility of elk, but not deer, seems to be modulated by codon 132, which corresponds to codon 129 in humans (Fig. 11). Elk with CWD consistently express Met/Met at position 132; no elk with CWD expressing leucine at this residue have been found.

15.2 Bovine Spongiform Encephalopathy

Prion strains and the species barrier are of paramount importance in understanding the BSE epidemic in Britain, in which it is estimated that between one and two million cattle were infected with prions. The mean incubation time for BSE is approximately 5 years. Therefore, most cattle did not manifest disease because they were slaughtered between 2 and 3 years of age. Nevertheless, more than 180 000 cattle, primarily dairy cows, have died of BSE over the past decade. BSE is a massive common-source epidemic caused by meat and bone meal (MBM) fed primarily to dairy cows. MBM was prepared from the offal of sheep, cattle, pigs, and chickens as a high-protein nutritional supplement. In the late 1970s, the hydrocarbon-solvent extraction method used in the rendering of offal began to be abandoned, resulting in MBM with a much higher fat content. It is now thought that this change allowed scrapie prions from sheep to survive the rendering process and to be passed into cattle. Alternatively, bovine prions may have been present at low levels prior to modification of the rendering process and with the processing change, survived in sufficient numbers to initiate the BSE epidemic when reintroduced into cattle through ingestion of MBM. Perhaps, a particular conformation of $BoPrP^{Sc}$ selected for heat-resistance during the rendering process and then reselected multiple times as cattle infected by ingesting prion-contaminated MBM were slaughtered and their offal rendered into more MBM. Against the latter hypothesis is the widespread geographical distribution of the initial 17 cases of BSE throughout England, which occurred almost simultaneously.

In July 1988, the practice of feeding MBM to sheep and cattle was banned. Although statistical analyses demonstrate that the epidemic is disappearing as a result of this ruminant feed ban, reminiscent of the disappearance of kuru in the Fore people of New Guinea, it is unclear how many current cases of BSE are due to infection and how many arise spontaneously. In 2003, there were 1390 cases of BSE; how many were due to tainted feed is unknown. Although evidence of a preexisting prion disease of

cattle, either in Great Britain or elsewhere, is scant, an outbreak of TME in Wisconsin has been cited as evidence for sporadic BSE. Moreover, the formation of synthetic prions from wt PrP argues that any mammal expressing PrP^C can produce prions spontaneously.

The origin of BSE prions cannot be determined by examining the amino acid sequence of PrP^{Sc} from cattle with BSE because it has the bovine sequence regardless of whether the initial prions originated from sheep or cattle. The bovine PrP sequence differs from that of sheep at seven or eight positions.

Brain extracts from cattle with BSE cause disease in cattle, sheep, mice, pigs, and mink after intracerebral inoculation, but prions in brain extracts from sheep with scrapie fed to cattle produced an illness substantially different from BSE. However, no exhaustive effort has been made to test different strains of sheep prions or to examine the disease following bovine-to-bovine passage.

15.3 Monitoring Cattle for BSE Prions

Although no reliable, specific test for prion disease in live animals is available, immunoassays for PrP^{Sc} in the brainstems of cattle currently provide the best available approach for preventing BSE prions from entering the human food supply. Determining how early in the incubation period PrP^{Sc} can be detected by immunological methods is now possible because a reliable bioassay is now available with the creation of Tg(BoPrP)$Prnp^{0/0}$ mice. Prior to the construction of Tg(BoPrP)$Prnp^{0/0}$ mice, cattle were used for bioassays of bovine prions. In a very limited study using cattle bioassays, bovine prions were undetectable in the obex of the brainstem until 26 months after oral inoculation. In these studies, prion infectivity was detected much earlier in the lymphoid tissue of the distal ileum.

Prior to development of Tg(BoPrP)$Prnp^{0/0}$ mice, non-Tg mice inoculated intracerebrally with BSE brain extracts required more than 300 days to develop disease. Generally, many of the inoculated mice fail to develop prion disease. It is noteworthy that a highly stable, mouse prion strain denoted 301V was derived by passage of BSE inocula into non-Tg $Prnp^{b/b}$ mice.

Both Western blots and ELISA tests are currently used in the postmortem evaluation of bovine brainstems. As configured, these tests are quite insensitive. The CDI, whose sensitivity is superior to conventional Western blots and ELISAs, offers a new approach to measuring PrP^{Sc} in tissues. The sensitivity of the CDI for BSE prions was found to be similar to that of bioassays using Tg(BoPrP)$Prnp^{0/0}$ mice. These studies suggest that the CDI may be able to detect BSE prions in asymptomatic cattle even when titers are quite low.

15.4 Compelling Evidence of Transmission of Bovine Prions to Humans

The restricted geographical occurrence and chronology of vCJD raise the possibility that BSE prions have been transmitted to humans. That only ~150 vCJD cases have been recorded and the incidence has remained relatively constant made establishing the origin of vCJD difficult. No set of dietary habits distinguishes vCJD patients from apparently healthy people. Moreover, there is no explanation for the predilection of vCJD for teenagers and young adults. Why have older individuals

not developed vCJD-based neuropathologic criteria? It is noteworthy that epidemiologic studies over the past three decades have failed to find evidence of transmission of sheep prions to humans. Attempts to predict the future number of cases of vCJD, assuming exposure to bovine prions prior to the offal ban, have been uninformative because so few cases of vCJD have occurred. Are we at the beginning of a prion disease epidemic in Britain, as seen for BSE and kuru, or will the number of vCJD cases remain small, as seen with iCJD caused by cadaveric HGH?

Recent studies of PrP^{Sc} from brains of patients who died of vCJD show a PrP glycoform pattern different from those found for sCJD and iCJD. The utility of measuring PrP glycoforms is questionable in trying to relate BSE to vCJD because PrP^{Sc} is formed after the protein is glycosylated and enzymatic deglycosylation of PrP^{Sc} requires denaturation. Moreover, synthetic prions have been formed from unglycosylated recMoPrP(89–230), demonstrating that glycosylation is unnecessary for prion formation.

Prior to the investigations recorded below laboratory studies were unconvincing in establishing a relationship between the conformations of PrP^{Sc} from cattle with BSE and those from humans with vCJD. Perhaps slightly more persuasive is the relationship demonstrated between vCJD and BSE based on similar incubation times in non-Tg RIII mice, of ~310 days after inoculation with human vCJD or bovine BSE prions. But such studies suffer from transmission of both BSE and vCJD prions to a heterologous host, that is, non-Tg mice expressing $MoPrP^{C}$. Using Tg mice, as was done for strains generated in the brains of patients with FFI or fCJD, compelling evidence for the transmission of bovine prions to humans was found. BSE prions transmitted to all inoculated Tg(BoPrP) mice after ~240 days but not to Tg mice expressing either HuPrP or MHu2MPrP. On second passage to Tg(BoPrP) $Prnp^{0/0}$ mice, the incubation time was unaltered, demonstrating the complete absence of a species barrier. Similar to BSE prions, vCJD prions transmitted readily to Tg(BoPrP) $Prnp^{0/0}$ mice, with a slightly longer incubation time of ~270 days, but poorly to Tg(HuPrP) and Tg(MHu2M) mice. Moreover, sCJD, iCJD, and fCJD(E200K) prions failed to transmit disease to Tg(BoPrP) mice after more than 500 days. On second passage of vCJD prions to Tg(BoPrP) $Prnp^{0/0}$ mice, the incubation time was reduced to ~225 days, demonstrating a small but expected species barrier. These findings argue that the strain-specific PrP^{Sc} conformations from BSE and vCJD prions are quite similar despite substantial differences in the amino acid sequences of BoPrP and HuPrP. Clearly, the conformation of $HuPrP^{Sc}$(vCJD) makes these prions much more readily transmittable to Tg(BoPrP) $Prnp^{0/0}$ mice than to either Tg(HuPrP) $Prnp^{0/0}$ or Tg(MHu2M) $Prnp^{0/0}$ mice.

15.5 Chronic Wasting Disease

Mule deer, white-tailed deer, and elk have been reported to develop CWD, which is unique among the prion diseases because it seems to be far more communicable than scrapie, BSE, or TME; moreover, it is the only prion disease known in free-ranging animals. CWD was first described in 1967 and reported to be a spongiform encephalopathy in 1978 based on histopathology in the brain. CWD has been found in the United States, Canada, and South Korea. In the United States,

CWD has been reported in Colorado, Wyoming, South Dakota, Nebraska, Oklahoma, Montana, New Mexico, Minnesota, and Wisconsin. In captive cervid herds, up to 90% of mule deer have been reported to be positive for prions and up to 60% of elk in Colorado and Wyoming develop CWD. Moreover, the incidence of CWD in cervids living in the wild has been estimated to be as high as 15%. The mode of transmission of CWD prion among mule deer, white-tailed deer, and elk is unresolved but contamination of grass with prions excreted in fecal matter seems to be a likely source. The high content of PrP^{Sc} in the intestinal lymphoid tissue of cervids with CWD supports such a scenario.

Brain homogenates from mule deer with CWD have transmitted disease to 4 of 13 cattle after intracerebral inoculation. These findings are particularly important because there is great concern that CWD prions might be transmitted to cattle grazing in contaminated pastures. In addition, CWD has been transmitted to ferrets, mink, squirrel monkeys, goats, and mice after intracerebral inoculation; however, only mule deer demonstrate efficient transmission of CWD prions by intracerebral inoculation. To date, endpoint titrations of CWD prions have not been performed in mule deer and Tg mice susceptible to CWD prions have not been developed, but the CDI has been adapted to measure CWD prions rapidly.

16
Fungal Prions

Although prions were originally defined in the context of an infectious pathogen, it is now becoming widely accepted that prions are elements that impart and propagate variability through multiple conformers of a normal, cellular protein. It is likely that such a mechanism will not be restricted to a single class of transmissible pathogens. Indeed, it is probable that this original definition will need to be extended to encompass other situations in which a similar mechanism of information transfer occurs. Two notable prion-like determinants, [*URE3*] and [*PSI*], have been described in yeast and another prion-like determinant has been reported in other fungi.

16.1
Yeast Prion Domains

In both [*PSI*] and [*URE3*], the ''functional'' determinants have been mapped to the C-terminal region of the protein, distinct from the ''prion'' domain, which comprises the N-terminal residues 65 and 114 of Ure2p and Sup35p, respectively. Although neither of the prion domains displays sequence identity either to each other or to PrP, the N-terminal regions of both Sup35p and mammalian PrP contain short repeated sequence elements: PQGGYQQYN in Sup35p and PHGGGWGQ in PrP. Interestingly, when the prion domains of both Sup35 and Ure2p are expressed in *E. coli* and purified, they polymerize spontaneously into amyloid-like fibrils. Polymerization of the prion domains of both Sup35 and Ure2p are able to create [*PSI*] and [*URE3*] states in yeast, respectively.

16.2
Dependence of Yeast Prions on Molecular Chaperones

The intrinsic power of the yeast genetic system has provided striking evidence of

the involvement of chaperones in the propagation of yeast [*PSI*] "prions." A genetic screen for factors that suppress the [*PSI*] phenotype resulted in the isolation of a single suppressor plasmid, which was found to contain the chaperone Hsp104. Furthermore, propagation of [*PSI*] was eliminated by either overproduction or absence of Hsp104, and treatment of cells with guanidine or UV light led to induction of Hsp104. The significance of Hsp104 is unclear because no published data exist to indicate that [*URE3*] utilizes Hsp104; furthermore, overexpression of Sup35 at high levels can induce [*PSI*] in the absence of Hsp104.

16.3 Differences between Yeast and Mammalian Prions

A wealth of studies has established the concept of fungal prions. While fungal prions are produced in the cytoplasm, mammalian prions are produced within cholesterol-rich microdomains on the surface of cells called *rafts* or *CLDs*. Whether the process of fungal and mammalian prion replication are fundamentally different or quite similar remains to be established. It seems likely that many more similarities than differences will emerge because distinct strains of both fungal and mammalian prions seem to represent different conformations of a particular protein. This finding necessitates a mechanism by which a particular conformation can be templated and reproduced with a high degree of fidelity.

Interestingly, the prion state in yeast is proposed to be functionally inert in the case of both [*PSI*] and [*URE3*] and produces the same phenotype as inactivation of the maintenance gene. In contrast, prion diseases in mammals cannot be explained simply by the loss of function of PrP because ablation of the PrP gene does not as yet have a detectable deleterious effect.

17 Prion Diseases are Disorders of Protein Conformation

The study of prions has followed several unexpected directions over the past three decades. The discovery that prion diseases in humans are uniquely genetic and infectious has greatly strengthened and extended the prion concept. To date, more than 30 different mutations in the human PrP gene, all resulting in nonconservative substitutions have been found either to be linked genetically to or to segregate with the inherited prion diseases (Fig. 11).

Understanding how PrP^{C} unfolds and refolds into PrP^{Sc} will be of paramount importance in transferring advances in the prion diseases to studies of other degenerative illnesses. The mechanism by which PrP^{Sc} is formed must involve a templating process in which existing PrP^{Sc} directs the refolding of PrP^{C} into nascent PrP^{Sc} with the same conformation. Undoubtedly, molecular chaperones of some type participate in a process that appears to be associated with CLDs on the cell surface.

Studies of prions in fungi have been extremely helpful in establishing the prion concept. In the case of yeast, Sup35 and Ure2p fold into alternative conformations that create the new metabolic states [*PSI*] and [*URE3*], respectively. Whether PrP^{Sc} in mammals represents a misfolded protein or an alternatively folded protein, as with yeast prions, remains to be established.

18 Prevention and Therapeutics for Prion Diseases

Because people at risk for inherited prion diseases can now be identified decades before neurologic dysfunction is evident, the development of an effective therapy for these fully penetrant disorders is imperative. Although it is difficult to predict the number of individuals who may develop neurologic dysfunction from bovine prions in the future, seeking an effective therapy now seems most prudent. Interfering with the conversion of PrP^{C} into PrP^{Sc} would seem to be the most attractive therapeutic target.

Defining the pathogenesis of prion disease is an important issue with respect to developing an effective therapy. The issue of whether large aggregates of misprocessed proteins or misfolded monomers (or oligomers) cause CNS degeneration has been addressed in several studies of prion diseases in humans as well as in Tg mice. In humans, the frequency of PrP amyloid plaques varies from 100% in GSS and vCJD to ~70% in kuru and ~10% in sCJD, arguing that these plaques are a nonobligatory feature of the disease. In Tg mice expressing both MoPrP and SHaPrP, animals inoculated with hamster prions produced hamster prions and developed amyloid plaques composed of $SHaPrP^{Sc}$. In contrast, Tg mice inoculated with mouse prions did not develop plaques even though they produced mouse prions and died of prion disease.

18.1 Prion Therapeutics

Various compounds have been proposed as potential therapeutics for treatment of prion diseases; these include polysulfated anions, dextrans, Congo red dye, oligonucleotides, and cyclic tetrapyrroles, all of which have been shown to increase survival time when given prior to prion infection in rodents, but not when administered a month or more after infection has been established.

Besides studies in rodents, ScN2a cells chronically infected with scrapie prions have been used to identify several candidate antiprion drugs but none have been shown to be effective in halting prion diseases in either animals or humans. Structure-based drug design based on dominant-negative inhibition of prion formation has produced several lead compounds. Prion replication depends on protein–protein interactions and a subset of these interactions gives rise to dominant-negative phenotypes produced by single residue substitutions. A particularly interesting set of drugs is the branched polyamines, or dendrimers, which enhance the clearance of PrP^{Sc} from cells. While these compounds cure cultured cells of prion infection, they have not been successfully deployed in mice because of difficulties in delivering such highly charged compounds to the CNS.

18.1.1 Quinacrine and other Acridine Derivatives

Tricyclic derivatives of acridine exhibit half-maximal inhibition of PrP^{Sc} formation at effective concentrations (IC_{50}) between 0.3 μM and 3 μM in cultured ScN2a cells. The IC_{50} for chlorpromazine was 3 μM while quinacrine was 10 times more potent. A variety of 9-substituted, acridine-based analogs of quinacrine were synthesized, which demonstrated variable potencies similar to chlorpromazine and emphasized the importance of the side chain in mediating the inhibition of PrP^{Sc}

formation. These studies showed that tricyclic compounds with an aliphatic side chain at the middle ring moiety constitute a new class of antiprion agents. Because quinacrine and chlorpromazine have been used for many years in humans as antimalarial and antipsychotic drugs, respectively, and are known to penetrate the blood-brain barrier (BBB), these compounds became immediate candidates for the treatment of CJD and other human prion diseases.

An asymmetric carbon in the side chain of quinacrine creates two stereoisomers. (*S*)-Quinacrine is two to three times more potent than the (*R*)-quinacrine enantiomer in cultured cells. Whether the use of (*S*)-quinacrine in place of the racemic mixture will allow significantly more drug to be given remains to be established. Studies performed almost six decades ago in humans demonstrated that (*S*)-quinacrine is selectively metabolized and that (*R*)-quinacrine remains intact. Whether (*R*)-quinacrine or the metabolites of (*S*)-quinacrine are responsible for the side effects recorded in patients receiving the racemic mixture is unknown. Side effects of quinacrine include liver toxicity, cardiomyopathy, and toxic psychoses.

18.1.2 Anti-PrP Antibodies

A panel of recombinant antibody fragments (recFabs), recognizing different epitopes on PrP, was studied with respect to inhibition of prion propagation in cultured ScN2a cells. Recombinant Fabs binding to PrP^{C} on the cell surface inhibited PrP^{Sc} formation in a dose-dependent manner. In ScN2a cells treated with the most potent recFab D18, prion replication was completely abolished and preexisting PrP^{Sc} rapidly cleared, suggesting that this antibody may cure established infection. The activity of recFab D18 is associated with its ability to recognize more completely the total population of PrP^{C} molecules on the cell surface than other recFabs and with the location of its epitope on PrP^{C}. In other studies, a monoclonal antibody, pH4, which is thought to bind to the same region of PrP as recFab D18, was found to inhibit prion accumulation in ScN2a cells.

Whether antibodies or Fabs can be effectively administered to humans for the prevention and treatment of prion diseases is unclear. Neither antibodies nor Fabs cross the BBB in high concentration so that delivery of these proteins to the CNS remains a critical issue.

It is notable that anti-PrP antibodies delivered by transgenetics or by injection were successful in blocking prion replication in mice inoculated intraperitoneally. The same anti-PrP antibodies were ineffective in treating prion infection initiated by intracerebral inoculation.

18.2 Dominant-negative Sheep

The production of domestic animals that do not replicate prions may also prove to be a practical way to prevent prion disease. Sheep encoding Arg/Arg at polymorphic position 171 seem resistant to scrapie; presumably, this was the genetic basis of Parry's scrapie eradication program in Great Britain 30 years ago. A more effective approach applying dominant-negative inhibition for producing prion-resistant domestic animals, including sheep and cattle, is probably the expression of PrP transgenes encoding K219 and/or R171 (Fig. 11). Such an approach has been evaluated in Tg mice and shown to be effective. In fact, the replacement of all sheep with Arg/Arg at codon 171 is underway in the Netherlands. Such an approach can

be instituted by artificial insemination using sperm from males homozygous for Arg/Arg at residue 171.

In comparison, a less practical approach is the production of PrP-deficient cattle and sheep. Although such animals would not be susceptible to prion disease, they might suffer some deleterious effects from the ablation of the PrP gene.

19 Some Principles of Prion Biology

Many principles of prion replication are clearly unprecedented in biology. As such, it is not surprising that some of these principles have been slow to be embraced. Although prion replication resembles viral replication superficially, the underlying principles are quite different. For example, in prion replication, the substrate is a host-encoded protein, PrP^{C}, which undergoes modification to form PrP^{Sc}, the only known component of the infectious prion particle. In contrast, viruses carry a DNA or RNA genome that is copied and directs the synthesis of most, if not all, of the viral proteins. The mature virion consists of a nucleic acid genome surrounded by a protein coat, whereas a prion appears to be composed of a dimer of PrP^{Sc}. When viruses pass from one species to another, they often replicate without any structural modification, whereas prions undergo a profound change. The prion adopts a new PrP sequence, which is encoded by the PrP gene of the current host. That change in amino acid sequence can result in a restriction of transmission for some species while making the new prion permissive to others. In viruses, different properties exhibited by distinct strains are encoded in the viral genome, whereas in prions, strain-specific properties are enciphered in the conformation of PrP^{Sc}.

19.1 Implications for Common Neurodegenerative Diseases

Understanding how PrP^{C} unfolds and refolds into PrP^{Sc} may also open new approaches to deciphering the causes of and to developing effective therapies for some common neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS). Whether or not therapies designed to prevent the conversion of PrP^{C} into PrP^{Sc} will be effective in these more common neurodegenerative diseases is unknown. Alternatively, developing a therapy for the prion diseases might provide a blueprint for designing somewhat different drugs for these common disorders. Like the inherited prion diseases, subsets of Alzheimer's disease and ALS are caused by mutations that result in nonconservative amino acid substitutions in proteins expressed in the CNS.

As knowledge about prions continues to expand, our understanding of how prions replicate and cause disease will undoubtedly evolve. It is important to add that many of the basic principles of prion biology are becoming increasingly well understood.

Keywords

Apoptosis
A physiological cell-suicide process whose mechanism is shared among the metazoans.

Bcl-2
An apoptosis inhibitory protein whose gene is often translocated in follicular lymphoma.

Caspase
A family of cysteine proteases that cleave their substrates after aspartic-acid residues.

Death Receptor
Members of the tumor necrosis factor (TNF) receptor family that send proapoptotic signals when ligated.

IAP
Member of the inhibitor of apoptosis protein family.

p53
A tumor-suppressor gene that is commonly mutated in human cancers.

Programmed Cell Death
Cell death carried out by a physiological process whose role is to cause the death of the cell.

Apoptosis is a physiological process of cell suicide that is implemented by activation of latent proteases that demolish vital cellular constituents. Apoptosis is used to sculpt the body during development, to maintain constant cell number by balancing cell production by mitosis, and to remove cells that are damaged or infected. Failure of cells to undergo apoptosis can lead to cancer and autoimmune disease, and inappropriate apoptosis may contribute to or cause organ damage in degenerative disease and ischemic vascular injury.

1 Introduction

All cells are mortal, and they can die in a number of ways. Cells may be killed if exposed to a physical insult, drug, toxin, or abnormal gene product that interferes with a process required for ongoing survival, or if they fail to receive the nutrients needed to maintain their metabolism. In vertebrates, this kind of cell death is relatively uncommon under physiological conditions. By far, the most common way by which cells die is by activating a physiological, genetically programmed, suicide mechanism (Fig. 1).

Physiological cell death – in which a cell dies by activating an endogenous process whose role is to kill the cell – has been observed in most multicellular organisms and some single-celled organisms. In single-celled organisms, it is used as a contingent strategy to protect a group of individuals by limiting spread of infection or by reducing the consumption of limited resources. In multicellular organisms, cell death is programmed to occur in particular cells in particular circumstances.

Animal cells undergoing physiological cell death typically exhibit an appearance that has been termed *apoptosis*. Apoptotic features include shrinkage of the cell, appearance of blebs in the plasma membrane, and condensation of the chromatin against the nuclear membrane. In culture, apoptotic cells subsequently lose the integrity of their plasma membranes, whereas within a tissue of an animal, apoptotic cells are rapidly engulfed by other cells and degraded in their lysosomes.

The molecular mechanism of apoptosis is shared amongst the metazoans. Although defensive (against pathogens) and developmental cell death occur commonly in plants, and some of the signaling pathways that regulate these processes resemble those found in apoptosis signaling in animals, the effector mechanism of physiological cell death in plants and animals appears to be different.

The key event in apoptosis is activation of a family of latent proteases, termed *caspases*. Numerous control and signaling pathways exist so that cells undergo apoptosis in response to developmental cues, at the appropriate time.

As well as being important for development and homeostasis of cell number, apoptosis is also involved in many disease processes, such as removal of infected or damaged cells. An increase or a decrease in the amount of apoptosis has been observed in many diseases. In some cases, defects in apoptosis signaling are the primary cause of disease, whereas, in other cases, the appearance of apoptotic cells is a consequence of the disease process.

A detailed understanding of apoptosis is important because it may allow development of new therapies to treat diseases in which cells die inappropriately or in which they fail to die when they should.

2 Mechanisms of Apoptosis

2.1 Effector Mechanism

The key event in apoptosis is the cleavage of intracellular proteins by a family of aspartate-specific cysteine proteases, termed *caspases*. Caspases exist within healthy cells as zymogens. Once activated, they cleave other proteins within the cell, after particular aspartic-acid residues. If enough of a protein required for a cell to maintain viability is cleaved, the cell will die. Within the tissues of animals, cells

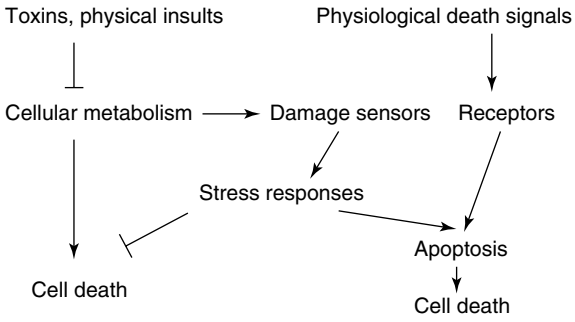

Fig. 1 All cells are mortal and can be killed if a vital metabolic process is blocked. If this process is only partially inhibited, a cell may detect the damage and mount a number of stress responses. Some of these responses protect the cell and repair the damage; however, cells may also respond to stress by committing suicide. Animal cells can activate their apoptotic cell-death mechanism either as a stress response or under normal physiological conditions to aid in development or to maintain homeostasis of cell number. Cells dying following noxious stimuli can simultaneously exhibit apoptotic and necrotic changes.

undergoing apoptosis are rapidly engulfed by neighboring cells or by specialist migratory phagocytic cells.

2.1.1 **Caspases**

Caspases are one of about 20 different classes of cysteine proteases, all of which cause cleavage of the peptide bond using catalytic cysteine and histidine residues. Caspases are intracellular endopeptidases that cleave their substrates, after aspartic-acid residues.

Mammals have genes for about 12 caspases. Some, such as caspases 1, 4, and 5 in humans and 1, 11, and 12 in mice, have roles in innate immunity by cleaving, and thereby activating prointerleukin 1β, but it is possible that these enzymes also function in apoptosis. Caspase-14 is thought to play a role in keratinocyte differentiation, but all other caspases (3, 6, 7, 8, 9, and human 10) are thought to be critical only for apoptosis.

As with all cysteine proteases, during proteolysis, the sulfur of the catalytic cysteine in caspases acts as a nucleophile, forming a thiol ester with the carbon of the substrate peptide bond, and then, the catalytic histidine provides a hydrogen to the nitrogen that follows, allowing separation of the peptide bond.

What makes caspases different from other cysteine proteases is the scaffold they use to align their substrate and to promote catalysis. These differences also account for the differences in substrate preference between individual caspases. While they all cleave after aspartic-acid residues, and they all prefer small residues such as glycine, serine or alanine to follow the aspartic acid, they show specific preferences for the P4–P2 residues. Caspase 3, for example, prefers to cleave substrates with an acidic P4 residue (e.g. . . .DEVD*G. . .), whereas caspase 9 prefers an aliphatic P4 (e.g. . .IETD*G. . .).

Caspases are synthesized as single-chain proenzymes (zymogens) that contain small (p10) and large (p20) subunits. The large subunit bears the catalytic cysteine and histidine residues, and residues in the small subunit help define substrate specificity.

Mammalian caspases can be grouped into two different classes on the basis of their substrate preferences, structure, and mode of activation.

The ''downstream'' or ''effector'' caspases 3, 6, and 7 account for most of the proteolytic activity in apoptotic cells. They have short prodomains at their amino-termini and are activated following cleavage of their zymogen forms by the ''upstream'' or ''initiator'' caspases (caspases 1, 2, 4, 5, 8, 9, 10, 11, and 12). In nonapoptotic cells, the effector caspases exist as dimers with very low zymogen activity. The two polypeptide chains that make up this dimer form catalytic sites in cis position once the flexible linkers that connect the small and large subunits of the monomers is cut by another caspase. The active form of effector caspases is a heterotetramer with two small (p10) subunits and two large (p20) subunits and two active sites. Thus, for effector caspases, their processing correlates well with their activity, and they are activated by proteolytic processing by an ''upstream'' or ''initiator'' caspase.

The ''upstream'' or ''initiator'' caspases (1, 2, 4, 5, 8, 9, 10, 11, and 12) exist as monomers in nonapoptotic cells. They have long amino-terminal prodomains bearing protein-interaction motifs, either CARDs (caspase recruitment domains) or DEDs (death effector domains), that allow them to bind to similar domains on caspase-activating adaptor molecules. Adaptor proteins promote activation of initiator caspases by inducing their dimerization or multimerization. Unlike the effector caspases, the initiator caspases do not need to be proteolytically processed in order to have significant activity. Nevertheless, once dimerized and activated, they can autoprocess, and this is thought to result in enhanced initiator-caspase activation. In addition, initiator caspases can be activated when cleaved by effector caspases, allowing a feed-forward cycle of caspase activation (Fig. 2).

2.1.2 **Caspase Substrates**

Several hundred potential caspase substrates have been identified by adding active caspases to cell extracts *in vitro* and by proteomic analysis of extracts of cells undergoing apoptosis. Currently, it is unclear which of these proteins must be cleaved for a cell to die, but cleavage of some cells has been shown to be important for some of the morphological or biochemical changes associated with

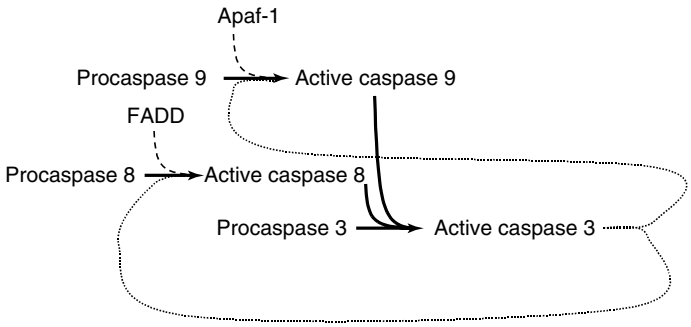

Fig. 2 Upstream caspases such as caspase 8 and caspase 9 are activated by dimerization induced by the adaptors FADD and Apaf-1 (dashed lines). These caspases can then cleave and activate downstream caspases such as caspase 3. Active, processed caspase 3 can feed back to cleave and activate further caspase 8 and caspase 9 (dotted lines).

apoptosis, such as membrane blebbing or DNA degradation.

Inhibitor of caspase activated DNAse (ICAD), for example, functions as a chaperone and inhibitor of the latent endonuclease CAD (caspase activated DNAse). After ICAD is cleaved by caspases, active CAD is liberated, which digests the cell's DNA. Cleavage of the Rho effector protein ROCK I by caspases generates a truncated active form that has been reported to be responsible for membrane blebbing seen in apoptosis.

2.1.3 Caspase Adaptor Proteins

Apaf-1 is the adaptor protein responsible for activating caspase 9. 'From the close similarity of mice deficient in caspase 9 with those deficient in Apaf-1, it is apparent that Apaf-1 is the main, if not the only, activator of caspase 9, and that Apaf-1 does not activate other caspases'? Apaf-1 bears a CARD domain that enables it to bind to the CARD of caspase 9. It also bears a nucleotide-binding P loop and a number of WD40 repeats. Apaf-1 is activated by binding to cytochrome *c* and dATP, and then, together with caspase 9, it aggregates into a large molecular-weight complex known as the "*apoptosome*." The apoptosome then recruits and activates caspase 3.

FADD is the adaptor responsible for activating caspase 8. Recruitment of FADD to aggregated members of the tumor necrosis factor (TNF) receptor family, which have an intracellular death domain (DD) (e.g. TNFR1, Fas and TRAIL receptors), occurs via DDsin FADD and results in formation of a complex known as the DISC (death inducing signaling complex). Within the DISC, FADD aggregates caspase 8 (and in humans, also caspase 10) through an interaction involving the DED of FADD and the two DEDs of procaspase 8 (or 10). The caspase then dimerizes, activates, and autoprocesses.

2.2 Control of Apoptosis

2.2.1 IAPs

Cell death can be controlled at multiple levels. For example, caspases can be controlled even after they are activated by the inhibitor of apoptosis (IAP) proteins. Four members of the IAP family, XIAP, cIAP1, cIAP2 and ML-IAP, have been shown to bind to and inhibit caspases, although XIAP has been the most extensively studied.

All the IAPs bear one to three copies of a domain, termed a BIR (baculoviral IAP repeat), that is a zinc-binding fold. Each of the antiapoptotic IAPs also carries a RING finger, another zinc-binding domain that allows IAPs to act as ubiquitin E3 ligases. Using their RING domains, IAPs can ubiquitinate themselves and other interacting proteins, targeting them for degradation by the proteasome.

XIAP, which has 3 BIRs, can inhibit apoptosis by binding to the catalytic sites of active caspases 3 and 7, via a region just amino-terminal to BIR2. XIAP can also bind via the core of BIR3 to the processed active caspase 9, thereby inhibiting it. Although XIAP binds to and inhibits caspases with high affinity, and can potently inhibit apoptosis of cultured cells exposed to certain stress stimuli, it has not yet been shown to confer long-term survival. Moreover, no major phenotype has been detected in those mice in which XIAP is deleted. It is, however, possible that IAPs have essential but overlapping functions in mammals, and interesting phenotypes may only appear in mice lacking two or more of these proteins.

2.2.2 **IAP Antagonists**

It has been clearly demonstrated that regulation of apoptosis by IAPs is very important in the fly, *Drosophila melanogaster*. Deletion of DIAP1 results in early embryonic lethality with massive apoptosis. In *Drosophila*, IAPs are themselves controlled by the proapoptotic IAP inhibitors, HID, Reaper, Grim, and Sickle, each of which bind to the core of BIR3 of DIAP1 to liberate active caspases. Two mammalian proteins, Smac/Diablo and HtrA2/Omi, have been identified that can bind to mammalian IAPs in a similar way and displace active caspases *in vitro*. Unlike the insect IAP antagonists, which are located in the cytoplasm, Smac/Diablo and HtrA2/Omi normally reside in the mitochondria such that they are only able to bind to IAPs and release caspases once the mitochondria are disrupted (Fig. 3). This may indicate that these mammalian IAP-binding proteins may regulate a caspase amplification mechanism rather than the initiation of the caspase cascade. Furthermore, unlike the insect IAP antagonists, Smac/Diablo is dispensable for normal development as Smac/Diablo-deficient mice are phenotypically normal and the primary role of HtrA2/Omi is to degrade or refold misfolded mitochondrial proteins, rather than to regulate apoptosis. As mentioned above, this may indicate that multiple IAP inhibitors have essential but overlapping functions in mammalian development.

2.2.3 **Bcl-2 Protein Family**

In addition to being controlled after their activation by IAPs, caspases are subject to regulation of their activation. Bcl-2, the product of a gene frequently translocated in human follicular center lymphoma, was initially identified as an inhibitor of cell death because it could prevent apoptosis of growth-factor-dependent cells deprived of cytokine. Three groups of Bcl-2-like proteins, all of which share one or more Bcl-2 homology (BH) domains, have now been identified. Some members, including mammalian Bcl-2, Bcl-xL, Bcl-w, A1/Bfl1, Mcl-1, Boo/Diva, *Caenorhabditis elegans* CED-9, and certain viral homologs such as adenovirus E1B19kD and Epstein Barr virus BHRF1, inhibit apoptosis. Bax, Bak, and Bok/Mtd share extensive sequence (2 or 3 BH domains) and structural homology with their prosurvival relatives, but they promote apoptosis and are essential for programmed apoptosis in a wide variety of circumstances. The third group, whose similarity is confined to a single BH3 domain (hence their name ''BH3-only proteins''), are also apoptosis promoters and are required for programmed cell death in response to many stimuli. This group includes proteins such as mammalian Bid,

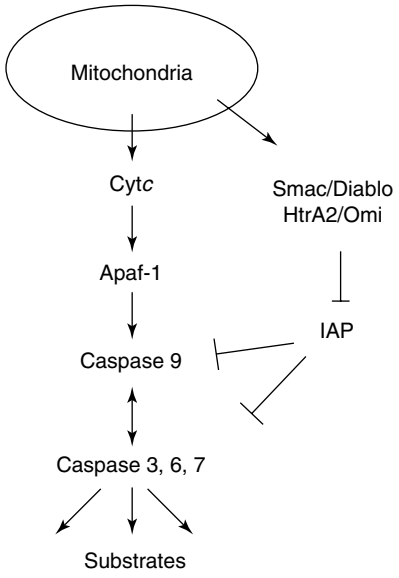

Fig. 3 IAPs can inhibit activated caspases, but they can be antagonized by proteins released from the mitochondria, such as Smac/Diablo and HtrA2/Omi.

Bik/Blk/Nbk, Bad, Bim/Bod, Hrk/DP5, Puma/Bbc3, Bcl-G_S, Noxa, and Bmf as well as *C. elegans* EGL-1.

Although Bcl-2 was the first component of the cell-death mechanism to be recognized, exactly how this component and its family members function remains controversial. There are two main models (Fig. 4). The first suggests that Bcl-2 functions like the *C. elegans* cell-death inhibitor CED-9, which acts by directly binding to the Apaf-1-like adaptor protein CED-4, thereby preventing it from activating the caspase CED-3. According to this model, Bcl-2 and other antiapoptotic family members prevent cell death by binding to CED-4-like adaptors to prevent them from activating caspases. In this model, apoptosis is triggered when proapoptotic Bax or Bak or BH3-only proteins bind to the antiapoptotic proteins, such as Bcl-2, and displace the adaptor proteins, thereby allowing them to activate initiator caspases. Genetic and biochemical studies have shown that BH3-only proteins and Bax/Bak-like proteins are both essential for apoptosis, but it is not clear how they interact biochemically. It is possible that the Bax/Bak-like proteins participate directly in the stimulation of adaptor proteins, but their function in caspase activation might be indirect.

The second model suggests that Bcl-2 prevents apoptosis by stopping release of proteins from the mitochondria. This idea achieved prominence when it was found

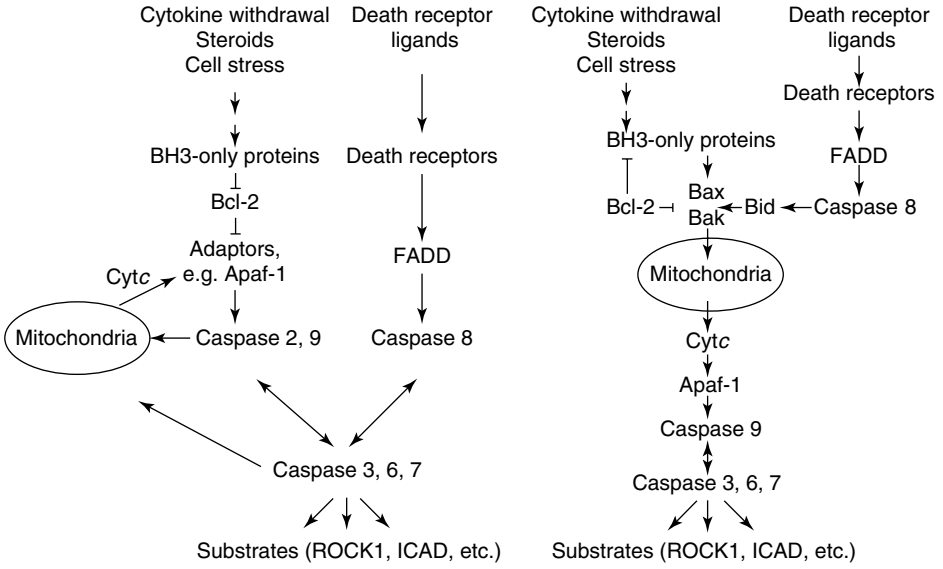

Fig. 4 Alternative models of the cell-death mechanism. In both models, independent pathways converge on a common effector mechanism. In the model (a), caspases are essential for apoptosis and the mitochondria play a nonessential role that serves to accelerate cell death. Bcl-2 promotes cell survival by preventing activation of caspases. In the model (b), the mitochondria play an obligatory role in cell death and caspases play a nonessential role as cells will die from loss of mitochondrial function, whether caspases are active or not. Bcl-2 promotes cell survival by preserving mitochondrial integrity.

that when released from the mitochondria into the cytosol, cytochrome *c* could bind to and activate Apaf-1, allowing it, in turn, to activate caspase 9. Since that time, it has been found that other proapoptotic proteins, such as Smac/Diablo and HtrA2/Omi, are also released from the mitochondria during apoptosis. According to this model, the proapoptotic Bcl-2 family members Bax and Bak form channels or pores in the mitochondrial outer membrane that directly or indirectly lead to release of apoptogenic proteins. In this model, the BH3-only proteins (directly or indirectly) cause changes in Bax and Bak that allow them to form the pores, and the antiapoptotic family members, such as Bcl-2, inhibit cell death by sequestering the BH3-only proteins.

The key difference between these models is that in the first, caspases are essential for apoptosis, and therefore, a pharmaceutical agent that can inhibit the relevant caspases would allow long-term survival of a cell. In this model, the critical events in mammalian apoptotic cell death would be similar to those in invertebrates, where experiments in the worm *C. elegans* have shown that the caspase CED-3 is required for all programmed cell deaths and experiments in *Drosophila* have shown that transgenic expression of the caspase inhibitor p35 prevents both programmed cell death and degenerative cell death in a retinitis pigmentosa model. In the second model, loss of mitochondrial function and release of mitochondrial proteins is the key event, so that even if caspase activity were blocked, cells would still die either because of loss of energy production by the mitochondria or, in a caspase independent manner, because of release of reactive oxygen species.

In both models, the proapoptotic signaling input comes from the BH3-only proteins. These proteins can integrate many different cell-death stimuli onto the apoptotic effector mechanism, and they themselves are regulated by a number of transcriptional and posttranslational mechanisms. Noxa and Puma/Bbc3 are transcriptionally upregulated by the tumor suppressor p53 and are therefore thought to be critical for DNA damage-induced apoptosis. Hrk/DP5 and Bim are induced by AP1 transcription factors, and Bim is also induced by the forkhead transcription-factor family member FKHRL1. Bim, Bmf, Bad, Bik, and Bid can be regulated at the posttranslational level. In healthy cells, Bim associates with microtubular dynein motor complex, and Bmf associates with the actin cytoskeleton-based myosin V motor complex, in such a way that they can be released following changes to the intracellular scaffolding. Bid is activated by proteolytic cleavage, for example, by caspase 8 or other caspases and may therefore form part of an amplification mechanism in the caspase cascade. Phosphorylation induced by cytokine-receptor stimulation allows Bad to be kept in an inactive state by sequestration to 14-3-3 scaffold proteins, and the proapoptotic activity of Bik/Blk/Nbk may instead be induced in response to phosphorylation.

In order to signal apoptosis, the BH3-only proteins bind to antiapoptotic members of the Bcl-2 family. The BH3 alpha helix of the BH3-only protein binds to a shallow groove on the surface of the antiapoptotic family member. In nonapoptotic cells, this groove may be occupied by the hydrophobic C-terminal tail of the antiapoptotic Bcl-2 family member. It is possible that binding of the BH3-only protein displaces the hydrophobic tail, which would then be free to interact with cellular membranes.

2.3 Cell-death Signaling Pathways

In mammalian cells, there are two distinct caspase-activation pathways. One is activated by members of the TNF receptor family with an intracellular DD (also known as *death receptors*, e.g. TNF-R1, Fas, TRAIL-R1, TRAIL-R2) and signals via the adaptor protein FADD to activate caspase 8. This pathway is known as the *death-receptor pathway*. It has also been called the *extrinsic pathway*, but this term is somewhat misleading because some of the stimuli that activate Bcl-2-regulated apoptosis signaling (see Sect. 3.1.3) are also extrinsic (e.g. addition of glucocorticoids or TGFβ). The nondeath receptor apoptosis-signaling pathway can be activated by stress conditions, such as removal of cytokines, addition of glucocorticoids, or DNA damage. In these cases, Bcl-2 is effective at blocking cell death, and release of cytochrome *c* from the mitochondria is an early feature. This pathway is known as the *Bcl-2-inhibitable pathway*, *intrinsic pathway*, or the *mitochondrial pathway*. We believe that the term "intrinsic pathway" is not entirely appropriate because, as mentioned above, this pathway can be activated by certain extrinsic stimuli, such as treatment with glucocorticoids or TGFβ. The term "mitochondrial pathway" is also problematic because, although in this pathway, mitochondria are damaged and apoptogenic molecules are released, there is now evidence that these changes are not essential for cell death but are a consequence of activation of caspases acting upstream.

2.3.1 Death-receptor Pathway

Ligation of members of the TNF receptor family with an intracellular DD (e.g. TNFR1, Fas, TRAIL-R1, and TRAIL-R2) can lead to apoptosis in a pathway that requires the adaptor molecule FADD and caspase 8 (with an involvement of caspase 10 in human cells). It should be noted that activation of caspase 8 and apoptosis is not the only event stimulated by these receptors, as ligand binding can also activate transcription factors NF-kB and Jun. Moreover, experiments with genetically modified mice have shown that in T lymphocytes, FADD is not only required for "death-receptor"-induced apoptosis but is also essential for mitogen-induced proliferation. It is believed that regulatory proteins, such as FLIP (which is induced by NF-kB), may prevent activation of caspase 8 by FADD and thereby allow other signaling functions of FADD to come to the fore.

Once caspase 8 is activated, it can directly cleave some protein substrates within the cell, but it also cleaves and activates effector caspases 3 and 7. Mitochondria lose their membrane potential and proteins such as cytochrome *c* and Smac/Diablo leave the mitochondria and enter the cytosol in death receptor–induced, caspase 8–dependent apoptosis. These events are dependent on caspase 8 activity because the mitochondrial events do not occur if caspase 8 is inhibited, for example, by the Cowpox-derived protein CrmA. In most cells, Bcl-2 family members do not play critical roles in death receptor–induced apoptosis as lymphocytes or myeloid cells in which Bcl-2 is overexpressed or Bax and Bak are deleted remain sensitive to Fas ligand.

Some believe that a subset of cells, known as *Type II cells*, activate less caspase 8 following death-receptor ligation such that death receptor–induced apoptosis in these cells can be partly inhibited by Bcl-2 family members. It is proposed that in these Type II cells, caspase 8 cleaves the

BH3-only protein Bid, which then activates the Bcl-2-inhibitable death pathway.

2.3.2 Bcl-2 Inhibitable Pathway

When apoptosis occurs after cytokine withdrawal, addition of glucocorticoids, or following cell stress caused by chemotherapeutic drugs, toxins, hypoxia, γ- or UV-radiation, or high temperature, it can almost always be inhibited by Bcl-2 (and its prosurvival homologs). It is very important to note, however, that inhibition of apoptosis by Bcl-2 will not necessarily save the cell; it will still die if a process essential for its continued survival is blocked but it will not exhibit the classical apoptotic morphology. The fact that cells commonly respond to sublethal damage by undergoing apoptosis means that many cells treated with toxins or chemotherapeutic drugs exhibit both apoptotic as well as necrotic changes.

2.4 Fate of Apoptotic Cells

In vivo, apoptotic cells are rapidly engulfed by either neighboring cells or professional phagocytes before they lyse. A key event in the recognition of apoptotic cells by the engulfing cells is the exposure of phosphatidylserine (PS) on the outer surface of the plasma membrane. In healthy cells, PS is maintained on the inner surface through an active process that is thought to be mediated by a translocase. While activation of the apoptotic effector machinery leads to rapid surface exposure of PS, it is not currently known how this happens, although it is presumed to be a caspase-dependent event that causes either inactivation of a PS translocase or activation of a PS scramblase.

Phosphatidylserine on the apoptotic cell is recognized by a specific receptor, termed the PSR, but other receptors, such as CD36, CD-14, and ABC1 and the integrins $\alpha_V\beta_5$ and $\alpha_V\beta_3$ as well as macrophage-secreted MFG-E8, are also implicated in the recognition of apoptotic cells by phagocytes. Binding of the apoptotic cell activates a signaling pathway within the engulfing cell that involves phosphorylation of p130 cas, recruitment of Crk-II and Dock-180, and activation of Rac-1, which ultimately causes formation of pseudopodia around the dying cell. Engulfed cells are then fully degraded within the lysosomal compartment.

3 Apoptosis in Normal Physiology

3.1.1 Development

Development in mammals, as in insects, worms, and possibly all multicellular organisms, is characterized by generation of excess cells, followed by removal of those that are not needed by apoptosis. For example, during development in *C. elegans*, 131 of the 1090 somatic cells formed are fated to undergo programmed cell death. When cell death is blocked, for example, by mutating the genes for the caspase CED-3, its activator CED-4, or the BH3-only protein EGL-1, most of the 131 cells that fail to die adopt the fate of their sister cells.

In vertebrates, apoptosis is used to remove interdigital tissue, allowing the fingers and toes to separate. It is also used to create hollow tubes and to remove epithelial cells when tissues fuse at the midline. It is estimated that over 80% of neurons formed during intrauterine development are destined to die by apoptosis in the perinatal period. Consistent with this, deletion of genes for proteins that promote apoptosis, such as Apaf-1, caspase 9, and caspase

3, lead to abnormal accumulation of neuronal cells, and animals often die perinatally with incomplete closure of the neural tube. However, when Apaf-1, caspase 9, or caspase 3 mutations are crossed onto the C57BL/6 background, the phenotype is much milder, and some apparently normal animals live to adulthood and reproduce, demonstrating that there is no absolute requirement for any of these proteins. Furthermore, clonogenic experiments have shown that in hemopoietic cells at least, neither Apaf-1, caspase 9, nor caspase 2 are required for cell death following cytokine withdrawal or treatment with cytotoxins, but are only required for rapid display of the classic apoptotic morphology.

3.1.2 Homeostasis

Apoptosis is also used to maintain constant cell numbers by balancing mitotic cell production. For example, if a lobe of the liver is removed, the hepatocytes in the remaining lobes of the liver grow and proliferate. Typically, there is an overshoot, but apoptosis occurs to bring the liver back to the appropriate size.

3.1.3 Immune System

The immune system uses apoptosis very extensively, both for selection of its repertoire of antigen-receptor specificities amongst lymphocytes and as a tool for combating pathogens. Developing B lymphocytes and thymocytes that fail to express antigen receptors cannot transmit signals to sustain their survival and undergo an apoptotic "death by neglect." In early B cells, this death is mediated by the Bcl-2 regulated pathway, and in T cell progenitors, it requires the caspase adaptor FADD, indicating an involvement of death receptors. Developing B and T cells with receptors that have a high affinity for a self antigen also undergo apoptotic "negative selection" that is important for the maintenance of tolerance to self, thus imposing a barrier against autoimmune disease. Experiments in genetically modified mice have shown that the BH3-only protein Bim is critical for negative selection and that Bcl-2 can inhibit this process. During an immune response, large numbers of effector B and T lymphocytes are produced, and at the end of the response, most of the cells undergo apoptosis, but a few "memory cells" remain. It appears that both Bcl-2-regulated apoptosis signaling that involves Bim as well as death-receptor signaling are involved in the culling of effector lymphocytes.

Cytotoxic T lymphocytes (CTL) kill virally infected cells by inducing them to undergo apoptosis. CTL can kill by two different mechanisms. The granule-exocytosis mechanism depends on perforin and calcium and involves introduction of components of the granules of CTL into the target cell. Among the granule components are several serine proteases termed *granzymes*. Unlike other serine proteases, but like the caspases, granzyme B has preference for cleaving after aspartic-acid residues. Granzyme B can cleave and activate caspases *in vitro* and can also cleave caspase substrates such as vital structural components of the cell and the BH3-only protein Bid.

Because they often express membrane-bound Fas ligand, CTL can also kill certain target cells that bear Fas. Comparison of mice lacking genes for perforin with those bearing mutations in the genes for Fas (*lpr*) or Fas ligand (*gld*) indicate that the perforin-dependent granule-exocytosis mechanism is much more important for CTL activity than Fas Ligand/Fas-dependent killing.

4 Apoptosis in Disease

4.1.1 Cancer

For a tumor to expand, the rate of cell division must exceed the rate of cell death. Although many oncogenes act by promoting cell proliferation, the association of translocations involving Bcl-2 with follicular lymphoma and the production of transgenic mice that overexpress Bcl-2 proved that inhibition of cell death could also be oncogenic. Furthermore, because mice bearing a transgene that stimulates cell division (c-*myc*) as well as a transgene that inhibits cell death (*bcl*-2) develop malignancies much more rapidly than mice bearing either of the transgenes alone, it is clear that promotion of cell division and inhibition of apoptosis are potently synergistic.

The gene most commonly mutated in human cancers encodes the tumor suppressor p53. In response to DNA damage, p53 becomes stabilized and functionally activated. p53 acts in two different ways to prevent the formation of tumors: it can promote production of the cell-cycle inhibitor p21, leading to arrest in G1 that allows time for the DNA to be repaired and it can promote apoptosis via the Bcl-2-inhibitable pathway. Precisely how p53 does this is not yet clear, but the favored model is that p53 induces transcription of the BH3-only proteins PUMA and Noxa.

Transgenically expressed Bcl-2 can prevent apoptosis of irradiated thymocytes, pre-B cells, and mature B and T lymphocytes as does deletion of p53, but p53−/−mice develop thymomas much more readily than Bcl-2-transgenic mice, so not all of the tumor-suppressor activity of p53 is due to its proapoptotic activity. On the other hand, because mutant mice lacking the cell-cycle inhibitor p21 also have much lower incidence of tumors than p53−/−mice, it appears that the proapoptotic as well as the cell-cycle regulatory functions of p53 are critical for its tumor-suppressive activity.

Mutations of proapoptotic genes and overexpression of antiapoptotic genes have been searched for in many different cancer types, but apart from translocations involving *bcl-2* and mutation of *p53*, these alterations are not common. Mice lacking Fas are prone to plasmacytoma development, and loss of FADD function promotes T lymphomagenesis in rag-deficient mice. Moreover, loss of Fas and Bcl-2 overexpression synergize potently in the development of myeloid leukemia in mice, demonstrating again that "death receptors" and Bcl-2 regulate distinct apoptosis-signaling pathways. Translocations involving cIAP2 are found in mucosa associated lymphoid tissue (MALT) lymphomas, but it seems unlikely that an antiapoptotic activity of cIAP2 is involved. Bax mutations have been found in some gastrointestinal tumors. Although there have been numerous reports of correlations between increased expression of cell-death inhibitors in cancers, or decreased expression of proapoptotic genes, a causal role has rarely been established, and an increased incidence of spontaneous tumors has not been reported to date in mice lacking genes for caspases, Apaf-1, Bax, Bak, or BH3-only proteins, or in mice transgenic for XIAP or CrmA.

In theory, increased expression of apoptosis inhibitors, or selection of cancer cells with higher levels of apoptosis inhibitors, may contribute to resistance to chemotherapeutic drugs. Because apoptosis, mediated via the Bcl-2 inhibitable pathway, is a common response to cell stress, including that caused by chemotherapeutic agents or γ-radiation, these drugs can cause cell

death in two very different ways. They can kill cells directly by interfering with a vital cellular process, such as protein synthesis or DNA replication, or they can kill cells indirectly by provoking an apoptotic stress response. At present, it is unclear which mechanism of cell death is more important for their therapeutic effect.

4.1.2 Autoimmune Disease

Transgenic mice that overexpress Bcl-2 and those lacking the proapoptotic genes for Bim, Fas (*lpr*), and Fas ligand (*gld*) develop autoimmune syndromes that resemble systemic lupus erythematosus. While these experiments and observations have proven that a properly regulated apoptotic mechanism is required to avoid autoimmune disease, the common human autoimmune diseases have rarely been found to be due to defects in cell-death genes.

Acute vascular disease Because hypoxia is one of the many cell stresses that can provoke an apoptotic response, it is possible that many of the neurons that die after a stroke, and the cardiomyocytes that die after a heart attack, are not dying purely from lack of oxygen but may be doing so because of activation of their apoptotic mechanism. Indeed, apoptotic cells have been found in hypoxic tissues of experimental animals, and experiments with first generation caspase-inhibitory drugs suggest that the total amount of cell death can be reduced by inhibiting apoptosis.

4.1.4 Sepsis

So far, the most promising results with antiapoptotic drugs have been obtained in preclinical studies of sepsis, where caspase inhibitors or Bcl-2 transgene expression in lymphocytes could prevent the death of mice that had undergone cecal ligation and puncture (CLP). Since Bcl-2 expression in lymphocytes only was effective, it appears that death or survival of effector lymphocytes determines the outcome of sepsis.

4.1.5 Degenerative Disease

Neurodegenerative diseases such as motor neurone disease, Parkinson's disease, and Alzheimer's disease are characterized by gradual loss of neurons. In some cases, signs have been found suggesting that this death is due to apoptosis, but because apoptosis is a rapid event, whereas progress of these diseases is chronic, it is very difficult to catch cells in the act of dying.

Because the processes that initiate these neurodegenerative diseases is still obscure, it may be that even if the cells ultimately die by apoptosis, they may have already been rendered nonfunctional by the primary abnormality, perhaps indicating that caspase-inhibitory drugs would not be able to halt or reverse tissue damage.

Nevertheless, the possibility that inhibiting apoptosis might retard progression of these diseases may justify trials of apoptosis inhibitors. The chronic nature of these diseases would necessitate long-term treatment, so it is likely that trials of cell-death inhibitors for neurodegenerative diseases will only occur after the inhibitors have been tested in more acute syndromes, such as septic shock (see Sect. 4.1.1).

Mice deficient for Bcl-2 die at an early age (3–6 weeks) from degenerative polycystic kidney disease and also have lymphopenia and abnormal melanocyte death, causing premature graying (Veis et al., 1993). All these defects could be prevented by concomitant loss of the BH3-only protein Bim; remarkably, loss of even

one allele of *bim* completely prevented polycystic kidney disease. This indicates that proapoptotic Bcl-2 family members may play critical roles in cell killing in degenerative diseases.

4.1.6 Infectious Disease

Cell death is an effective strategy to combat viral infections because viruses need to subvert the machinery of an intact cell in order to replicate. A cell that can detect the presence of a viral particle and respond by activating its apoptotic mechanism can prevent the virus from reproducing and infecting further cells.

This apoptotic antiviral strategy has put selective pressure on viruses to carry genes for apoptosis inhibitors. For example, certain baculoviruses (which infect insect cells) encode the caspase inhibitors p35 and IAP, cowpox virus carries the caspase-1 and -8 inhibitor CrmA, and many herpes viruses as well as adenoviruses, Epstein Barr virus and African Swine Fever Virus, encode Bcl-2 homologs.

4.2 Therapeutics

Hopefully, this understanding of the mechanisms of apoptosis will allow development of drugs to treat diseases in which there is either failure of or inappropriate apoptosis. With the benefit of hindsight, it is now clear that several therapies that were found to be useful empirically, such as γ-radiation, glucocorticoids, TNF antagonists, and some monoclonal antibodies, work to a significant extent by promoting or inhibiting apoptosis.

New caspase inhibitors, death-receptor agonists or antagonists, as well as inhibitors of anti- or proapoptotic Bcl-2 family members are likely to be tested in the clinic in the near future.

Bibliography 661
Books and Reviews 661
Primary Literature 661

Keywords

Combinatorial Biosynthesis
Genetic method used to generate novel natural compounds.

Functional Food
Food that is selected and advertised for a high content of therapeutically active molecules.

Genetic Engineering
Process of manipulating genes in an organism, mostly outside of its reproductive process.

Genome Mining
Genetic method to detect strains that are able to produce a given compound.

Glycorandomization
Method to generate novel glycosylated products.

Metabolic Engineering
Modification of cellular metabolism and properties by introducing, deleting, and modifying metabolic pathways.

Molecular Farming
Use of plants as biopharming systems for production of pharmaceutical proteins.

Mutasynthesis
Process to produce novel compounds by feeding an alternative precursor to a mutated strain.

Polyketides
Natural compounds derived from acetate.

Streptomyces
Bacteria, used for the production of antibiotics.

Transgenic Plant
Plant transfected with plasmids as vectors carrying the desired gene.

The production of compounds used in the food and pharmaceutical industries by biotech processes is both an old and a very young business. Over the past 70 years, fermentation of microorganisms or the use of yeast and plants in the production of important pharmaceuticals has been well established. The promises of genomics in drug discovery and drug production have now been fulfilled in many areas.

Bacterial strains, especially Actinomycetes have been used in biotech production and drug discovery for years. Genetic methods now open the field of combinatorial biosynthesis that has improved impressingly in the past couple of years. Also, the productivity of yeast and other fungi in a variety of different processes has improved significantly since genetic methods have been introduced. In addition, a number of recent works considerably widens the potential of plant biotechnology. This review covers examples describing the use of prokaryotic cells and plant cells in biotech production.

1
Actinomycetes in Biotech Production

Soil bacteria of the order Actinomycetes are the most important producers of pharmaceutically relevant bioactive metabolites including antibiotics, antitumor agents, immunosuppressants, antiparasitic agents, herbicides, and enzyme-inhibiting agents. The success story of these bacteria began about 60 years ago with the groundbreaking work of Waksman, who discovered and described streptomycin as the first antibiotic synthesized by an Actinomycete. Ever since, systematic large-scale screens performed by the pharmaceutical industry have revealed numerous therapeutically relevant drugs. More than two-thirds of all naturally derived antibiotics currently used are produced by Actinomycetes strains, underlining their importance to medicine.

1.1
Actinomycetes: Producer of Commercially Important Drugs

Natural products (''secondary metabolites'') have been the largest contributors to drugs in the history of medicine. Before antibiotics were introduced in the 1940s and 1950s (see above), patients with bacteremia faced low survival chances, and the mortality from tuberculosis was 50%. It has been stated that the doubling of our life span in the twentieth century is mainly due to the use of plant and microbial secondary metabolites. Of the 520 new drugs approved between 1983 and 1994, 39% were natural products or those derived from natural products and 60 to 80% of antibacterial and anticancer drugs were derived from natural products. Almost half of the best-selling pharmaceuticals are natural or related to them. In 2001, over 100 natural product–derived compounds were in clinical development. Natural products and their derivatives account for annual revenues of about US$30 billion in the anti-infectives market, US$20 billion in the anticancer market, and US$14 billion in the lipid-lowering market. Actinomycetes and, particularly, Streptomycetes (Fig. 1) are the largest antibiotic-producing genus in the microbial world discovered so far. Of the 12 000 or so antibiotics known in 1995, 55% were produced by Streptomycetes and an additional 11% by other

Actinomycetes. A compilation of numerous bioactive and commercially important metabolites, which are all synthesized by Actinomycetes strains, is shown in Table 1. This list includes not only very important drugs such as the macrolide erythromycin A synthesized by *Saccharopolyspora (Sac.) erythraea* (in 2000, the annual sales of semisynthetic derivatives reached US$2.6 billion), the glycopeptide vancomycin synthesized by *Amycolatopsis (A.) orientalis* (in 2000, the annual sales of glycopeptides reached US$424 million,) and tetracycline synthesized by *Streptomyces (S.) aureofaciens* (in 2000, the annual sales reached US$217 million) but also anticancer agents like doxorubicin synthesized by *Streptomyces peucetius* (Fig. 2). Many compounds produced by Actinomycetes belong to the large family of polyketides. Polyketides are structurally diverse (Fig. 2) and exhibit a wide scope of bioactivities. More than 500 aromatic polyketides have been characterized from

Tab. 1 Origin, target, and application of commercially important secondary metabolites originating from actinomycetes.

Antibiotic	***Producer***	***Molecular target***	***Application***
A40 926	*Nonomurea* sp.	Cell wall synthesis	Antibacterial
Amphotericin	*S. nodosus*	Membrane (pore-formation)	Antifungal
Ascomycin (FK520)	*S. hygroscopicus*	FKBP12	Immunosuppressive
Avermectin	*S. avermitilis*	Membrane (ion-channel)	Antiparasitic
Avilamycin	*S. viridochromogenes*	Ribosome	Antibacterial
Avoparcin	*A. coloradensis*	Cell wall synthesis	Antibacterial growth promotant
Bleomycin	*S. verticillus*	DNA binding	Antitumor

Antibiotic	*Producer*	*Molecular target*	*Application*
Clavulanic acid	*S. clavuligerus*	Beta-lactamases	Combined with β-lactam antibacterial
Chloramphenicol	*S. venezuelae*	Ribosome	Antibacterial
Chlortetracycline	*S. aureofaciens*	Ribosome	Antibacterial
Cyclohexamide	*S. griseus*	Ribosome	Antibiotic
Dactinomycin	*S. parvulus*	DNA intercalation	Antitumor
Daptomycin	*S. roseosporus*	Cell wall synthesis	Antibacterial
Daunorubicin	*S. peucetius*	DNA intercalation	Antitumor
Doxorubicin	*S. peucetius var caesius*	DNA intercalation	Antitumor
Erythromycin A	*Saccharopolyspora erythraea*	Ribosome	Antibacterial
Gentamicin	*Micromonospora purpurea*	Ribosome	Antibacterial
Geldanamycin	*S. hygroscopicus*	Hsp90	Antitumor
Kanamycin	*S. kanamyceticus*	Ribosome	Antibacterial
Lincomycin	*S. lincolnensis*	Ribosome	Antibacterial
Milbemycin	*S. hygroscopicus*	Membrane (ion-channel)	Antiparasitic
Mithramycin	*S. argillaceus*	DNA alkylation	Antitumor
Mitomycin C	*S. lavendulae*	DNA alkylation	Antitumor
Moenomycin	*S. ghanaensis*	Cell wall synthesis	Antibacterial, growth promotant
Monensin	*S. cinnamonensis*	Membrane (ionophore)	Anticoccidial, growth promotant
Natamycin	*S. nataensis*	Membrane (pore-formation)	Antifungal
Neomycin	*S. fradiae*	Ribosome	Antibacterial
Nikkomycin	*S. tendae*	Chitin synthase	Antifungal
Novobiocin	*S. niveus*	DNA gyrase	Antibacterial
Nystatin	*S. noursei*	Membrane (pore-formation)	Antifungal
Oxytetracycline	*S. rimosus*	Ribosome	Antibacterial
Pristinamycin	*S. pristinaespiralis*	Ribosome	Antibacterial
Ramoplanin	*Actinoplanes spec.*	Cell wall synthesis	Antibacterial
Rapamycin	*S. hygroscopicus*	FKBP	Immunosuppressive
Rifamycin	*A. mediterranei*	RNA polymerase	Antibacterial
Salinomycin	*S. albus*	Membrane (ionophore)	Anticoccidial, growth promotant
Spinosyn	*Sac. spinosa*	unknown	Insecticidal
Spiramycin	*S. ambofaciens*	Ribosome	Antibacterial
Staurosporin	*S. staurosporeus*	Protein kinase C	Antibacterial
Streptomycin	*S. griseus*	Ribosome	Antibacterial
Tacrolimus (FK506)	*Streptomyces spec.*	FKBP	Immunosuppressive
Teicoplanin	*A. teicomyceticus*	Cell wall synthesis	Antibacterial
Tetracycline	*S. aureofaciens*	Ribosome	Antibacterial
Thienamycin	*S. cattleya*	Cell wall synthesis	Antibacterial
Tylosin	*S. fradiae*	Ribosome	Growth promotant
Vancomycin	*A. orientalis*	Cell wall synthesis	Antibacterial
Virginiamycin	*S. virginiae*	Ribosome	Growth promotant

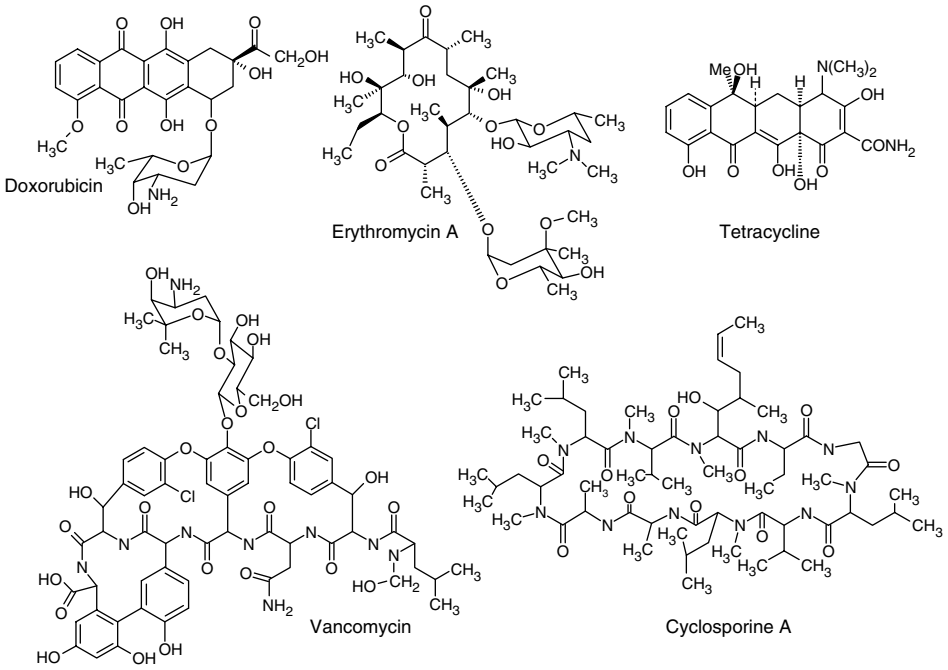

Fig. 2 Structures of natural compounds used as important drugs in pharmacy and medicine.

Actinomycetes. Polyketides are particularly important for drug discovery, since statistics show that 1 out of 100 polyketides will make its way to commercialization. With an average of as low as 1 out of 5000 compounds, other substances are far less likely to hit the market. Sales of drugs based on polyketides exceed US$15 billion a year. In general, for industrial production, overproducing strains have to be developed. Today, modern processes allow the production of compounds at concentrations even higher than 10 g L^{-1}.

1.2 Actinomycetes Genetics: The Basis for Understanding Antibiotic Biosynthesis

Streptomyces coelicolor A3 (2) is the genetically best-characterized strain among the filamentous Actinomycetes. Actinomycetes genetics has been the subject of research since 1958 when Prof. Dr. Sir D. Hopwood published the first linkage map of *S. coelicolor* performing the first genetic recombination experiments considering six marker genes. Afterwards, Actinomycetes genetics developed continuously, by the identification of mutants interrupted in the biosynthesis of actinorhodin. After identification and isolation of easily selectable antibiotic resistance genes, the first gene cloning in *Streptomyces* was described in 1980. In 1984, Malpartida and Hopwood demonstrated for the first time that antibiotic biosynthesis genes are usually organized as a gene cluster of structural, regulatory, export, and self-resistant genes. Hence, once a single gene within a cluster has been located, the others may be identified quickly by chromosomal

walking. In the course of the last two decades, many molecular tools including vector systems (phage and plasmid-based) have been developed along with DNA transfer and gene inactivation techniques, which were all necessary for targeted manipulation of Actinomycetes. The excellent manual published by the John Innes Institute summarizes all the necessary information related to handling and molecular genetic tools essential for working with Actinomycetes. Several hundred biosynthetic gene clusters have so far been identified and genes encoding about 80 pathways for secondary metabolites have been cloned, at least partially sequenced and made available to the public. The average size of an antibiotic biosynthetic gene cluster ranges from about 20 kb for a simple aromatic polyketide like actinorhodin to 120 kb for complex polyketides like the antifungal antibiotic nystatin.

A highlight in Actinomycetes genetics was the completion of the first genome sequence of the model Actinomycete *S. coelicolor*A3(2) in July 2001. Recently, the genome sequence of a second *Streptomyces* strain, the avermectin producer *Streptomyces avermitilis*, has been published, opening up new perspectives for comparative genomics with Actinomycetes. A characteristic feature of Actinomycete chromosomes is their linear structure. The genome of *S. coelicolor* comprises 8 667 507 bp (G/C content of 72.1%), whereas the *S. avermitilis* genome contains 9 025 608 bp (G/C content of 70.7%). Both genomes are densely packed and harbor 7574 ORFs in *S. avermitilis* and 7825 ORFs in *S. coelicolor*, respectively. Comparative analysis of the *S. coelicolor* and *S. avermitilis* chromosomes revealed that both the genomes had an unusual biphasic structure with a core region of 5 and 6.5 Mb, respectively. The most interesting feature in both the completed *Streptomyces* genomes that will impact biotechnology is the abundance of secondary metabolite gene clusters. Before the genome of *S. coelicolor* was sequenced, three antibiotics and a spore pigment were known to be synthesized from this strain. The genome sequence revealed that 23 gene clusters (about 5% of the total genome) are directly dedicated to secondary metabolism including clusters for further putative antibiotics, pigments, complex lipids, signaling molecules, and iron-scavenging siderophores. In *S. avermitilis*, 30 gene clusters related to secondary metabolites were identified, corresponding to 6.6% of the genome. From these clusters, 5 out of 30 are putatively involved in pigments and siderophores, 5 in terpenes, 8 in nonribosomal peptides, and 12 in polyketide biosynthesis. With avermectin, oligomycin, and a polyene antibiotic, only three complex polyketide clusters have been characterized from this strain before. The completed genome-sequence data can also be used to study the regulatory network of primary metabolism pathways and the cross talk between primary and secondary metabolism (i.e. the carbon flux). The knowledge gained by these analyses will be useful for the construction of improved strains produced in a rational approach by deleting undesired pathways or adding advantageous pathways, generating precursors and essential cofactors. Moreover, targeted modifications will improve cell growth and fermentation properties (metabolic engineering). Successful metabolic engineering of a strain producing doramectin, a commercial antiparasitic avermectin analog, is an excellent example of the importance of this technology.

1.3 Urgent Need for the Development of New Antimicrobial Drugs

Stimulated by the discovery of numerous novel antibacterial agents, which reached a peak in the 1970s, US Surgeon General William Stewart declared in 1969 in the US Congress that it was ''time to close the book on infection diseases.'' Today, unfortunately, we know that antibiotics have not won the fight against infectious microorganisms and therefore there is a permanent need for new antibiotics.

One main reason for this development is the problem of emerging resistant forms of pathogens. As an example, according to the WHO more than 95% of *Staphylococcus aureus* strains worldwide are resistant to penicillin G, and up to 60% are resistant to its derivative methicillin. Several reasons (e.g. use of antibiotics as growth promoters, changes in the spectrum of pathogens) are responsible for this development.

The past decades witnessed a major decrease in the number of newly discovered compounds. In an almost 40-year period (1962–2000), no new class of antibiotic was introduced to the market (nalidixic acid in 1962, the oxazolidinone antibiotic linezolid in 2000). The major reason for the decrease in the number of newly discovered compounds might be a decline in screening efforts. Ironically, some of the leading pharmaceutical companies are currently cutting back their antiinfective programs, especially for natural products. They would rather focus their activities on the semisynthetic modification of existing antibiotics to produce second- and third-generation antibiotics with improved properties.

Nevertheless, there is no need to resign. According to biomathematical modeling, only 3% of all antibacterial agents synthesized in *Streptomyces* have been reported so far. Additionally, less than 10% of the world's biodiversity has been tested for biological activity, and many more useful natural lead compounds are yet to be discovered.

1.4 Strategies for the Identification and Development of New Antimicrobial Drugs

1.4.1 Approaches to Explore Nature's Chemical Diversity

Vicuron Pharmaceuticals Inc., formerly Biosearch Italia, a company screening for new antibiotics, focuses its activities on a proprietary strain collection of 50 000 microorganisms, including unusual filamentous Actinomycetes and filamentous fungi or strains that are difficult to isolate. The rationale behind this campaign is that these organisms have not been intensively screened in the past and that they may be producers of novel compound classes.

Another strategy to reveal the chemical diversity of a single strain is the One strain – many Compounds (OSMAC) approach described by Bode et al. By systematic alteration of cultivation parameters, the number of secondary metabolites increased tremendously in a single strain. When this method was applied, up to 20 different metabolites with, in some cases, high production titers were detected. Since recent estimates suggest that only 0.1 to 1% of the microbial flora in the environment can be kept in culture, the ''metagenome'' of the unculturable microorganisms should also have a potential to generate novel secondary metabolites. Indeed, several reports demonstrated that it is possible to construct DNA libraries from ''soil-DNA'' and to use them for the production of novel metabolites in a heterologous *Streptomyces* host.

1.4.2 Exploiting the Enormous Genotypic Potential of Actinomycetes by "Genome Mining"

The completion of the sequence of the two *Streptomyces* genomes demonstrated that between 5 and 6.6% of the whole genome are directly involved in the biosynthesis of predominantly unknown secondary metabolites (see above). Prior to genome sequencing, a number of reports were published in which cryptic or silent secondary metabolite pathways were identified during the search for gene clusters for known metabolites. Hence, the occurrence of multiple "orphan" gene clusters has been reported for various compound classes like nonribosomal peptides, PKSI and PKSII. Combinature Biopharm AG is a Berlin-based company using modern high-throughput genomics for the systematic genetic screening of several Actinomycetes genomes to identify known and "orphan" clusters. Recently, Zazopoulos et al. described how a genomics-guided approach can be rewarding for the discovery and expression of cryptic metabolic pathways (genome mining). The genetic information of these biosynthesis clusters is used for the targeted generation and modification of novel compounds in an approach termed "*combinatorial biosynthesis.*"

1.4.3 Generation of Novel Antibiotics by Targeted Manipulation of the Biosynthesis (Combinatorial Biosynthesis)

Researchers have started using biosynthetic genes to alter the structure of natural compounds by genetic engineering or to combine genes from different biosynthetic pathways. This new technology named *combinatorial biosynthesis* results in the formation of novel natural products.

New drugs by targeted gene disruption Inactivation of specific selected genes is a very common methodology for the generation of novel structural variations of known natural products. Erythromycin is a macrolide antibiotic that is clinically useful in the treatment of infections by gram-positive bacteria. A hydroxyl group at C6 of the erythronolide macrolactone is responsible for acidic inactivation in the stomach by conversion into anhydroerythromycin. Erythromycin derivatives lacking this hydroxyl group are therefore interesting from the therapeutic and pharmacological point of view. The gene *eryF* that encodes a cytochrome P450 monooxygenase responsible for the introduction of this hydroxyl group into the macrolactone was inactivated and the mutant produced 6- deoxyerythromycin A. This is a much more acid-stable antibiotic and as efficient as erythromycin because of its higher stability.

The orthosomycins are a prominent class of antibiotics produced by various Actinomycetes. Members of this class are active against a broad range of gram-positive pathogenic bacteria. Prominent examples of orthosomycins are the avilamycins and the everninomicins produced by *Streptomyces viridochromogenes* Tü57 and *Micromonospora carbonacea*, respectively. Avilamycins and everninomicins are poorly soluble in water, which poses a major obstacle for their use as therapeutics. The avilamycin biosynthetic gene cluster has been cloned and sequenced. Several putative methyltransferase genes have been found in the cluster. Double and triple mutants have been generated by deleting two or three methyltransferase genes in the chromosome of the producer strain (Fig. 3). All mutants produced novel avilamycin derivatives with improved water solubility.

Improved yield by expression of genes Pristinamycin, produced by *Streptomyces*

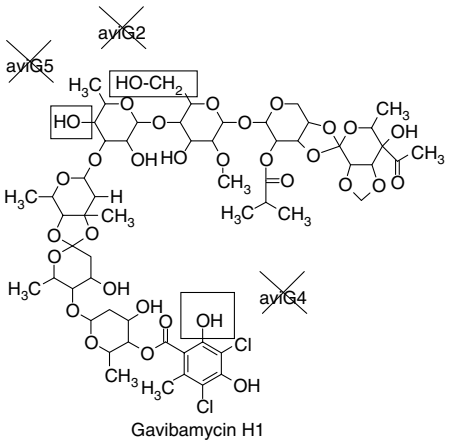

Fig. 3 Production of gavibamycin H1 by a mutant with deletions in three methyltransferase genes

pristinaespiralis, is a mixture of two types of macro-cyclic lactone peptolides, pristinamycins I (PI), a branched cyclic hexadepsipeptide of the streptogramin B group, and pristinamycins II (PII), a polyunsaturated cyclic peptolide of the streptogramin A group. Both the compounds inhibit the growth of bacteria. In combination, they display a synergistic bactericidal activity. The PII component of pristinamycin is produced mainly in two forms, called *PIIA* (80%) *and PIIB* (20%). A water-soluble derivative of pristinamycin, now being marketed under the trade name Synercid, was obtained by the chemical modification of PIIA. To generate a PIIA-specific producer strain, two genes, *snaA* and *snaB*, were isolated from the biosynthetic gene cluster. The enzymes encoded by *snaA* and *snaB* catalyze the conversion of PIIB to PIIA. Both genes were placed under the transcription control of a strong promoter and were cloned into an integrative vector. The integration of this vector into the chromosome of the producer strain resulted in the production of 100% PIIA and this was achieved in high concentrations.

New drugs by expression of genes Mithramycin is an aromatic polyketide, which is clinically used as an anticancer agent. It possesses a tricyclic chromophore and is glycosylated at two different positions. Urdamycin A is an angucycline polyketide produced by *Streptomyces fradiae* Tü2717, which also shows antitumor activity. It consists of the aglycon aquayamycin, which contains a C-glycosidically linked D-olivose, and three additional O-glycosidically linked deoxyhexoses. The UrdGT2 glycosyltransferase catalyzes the C-glycosyl transfer of activated D-olivose as the first glycosylation step during the urdamycin biosynthesis. Landomycins are produced by *S Streptomyces cyanogenus* S136 and contain an unusual hexasaccharide consisting of four D-olivose and two L-rhodinose units. These polyketides also show antitumor activities, in particular, against prostate cancer cell lines. To generate novel compounds, genes out of the urdamycin and landomycin clusters were expressed in mutants of *Streptomyces argillaceus*: coexpression of *urdGT2* (urdamycin biosynthesis) together with *lanGT1*, (landomycin biosynthesis) in a mutant of the mithramycin producer led to the hybrid molecule 9-C-diolivosyl-premithramycinone. This example was

listed as a highlight in the field of combinatorial biosynthesis as genes from three different organisms yielded a rationally designed product (Fig. 4).

Recently, a plasmid-based strategy has been described that allows the use of deoxysugar biosynthetic genes to produce a variety of deoxysugars in a cell, which can then be attached to an aglycon by the use of different glycosyltransferases. As an example, a plasmid was generated harboring all the genes necessary for the biosynthesis dTDP-D-olivose. This plasmid was coexpressed with the highly substrate-flexible glycosyltransferase gene *elmG* in *S. albus*. When 8-demethyltetracenomycin C was fed to this strain, D-olivosyltetracenomycin was produced. In a similar way, L-rhamnosyl-tetracenomycin C, L-olivosyl-tetracenomycin C, and L-rhodinosyl-tetracenomycin C were generated depending on the deoxysugar biosynthetic genes used in each case.

Polyketides are synthesized by the action of polyketide synthases (PKSs), which have been classified into two types, type I (modular PKSs) and type II (iterative PKSs).

Modular PKSs are large multifunctional enzymes. Active sites (domains) within these enzymes ketosynthases (KS), acyltransferases (AT), dehydratases (DH), enoyl reductases (ER), ketoreductases (KR), acyl carrier proteins (ACP) and thioesterases (TE) are organized into modules such that each module catalyzes the stereospecific addition of a new monomer onto a growing polyketide chain and also sets the reduction level of the carbon atoms of the resulting intermediate. In 1994, the heterologous expression of the complete erythromycin polyketide synthase was accomplished. The recombinant strain produced 6-deoxyerythronolide B. This polyketide synthase was then used for a variety of experiments in which modules/domains of the polyketide synthase were exchanged. As an example, compounds produced by the substitution of KR domains are shown in Fig. 5. In these examples, KR domains from the erythromycin PKS have been replaced by domains from the rapamycin producer.

New drugs by expression of "Artificial" genes UrdGT1b and UrdGT1c, involved in urdamycin biosynthesis, share 91% identical amino acids. However, the two GTs show different specificities for both nucleotide sugar and acceptor substrate. Targeted amino acid exchanges reduced the number of amino acids, potentially dictating the substrate specificity to 10 in either enzyme. Subsequently, a gene library was created such that only codons of these 10 amino acids from both parental genes were independently combined. Screening of almost 600 library members *in vivo* revealed 40 active members, acting either like the parental enzymes UrdGT1b and UrdGT1c or displaying a novel specificity. The novel enzymatic specificity is responsible for the biosynthesis of urdamycin P carrying a branched saccharide side chain, hitherto unknown for urdamycins (Fig. 6).

1.4.4 Novel Natural Compounds by Glycorandomization

As discussed above, combinatorial biosynthesis represents an *in vivo* methodology to diversify natural products, and, among them, numerous glycosides. It is superior to traditional synthetic chemistry in that it makes use of specific enzymes for efficient modifications of complex scaffolds and avoids solubility problems. The reactions are fed out of the host's metabolism, and its cytoplasm is used as an aqueous phase instead of toxic organic solvents that need to be carefully removed from the product

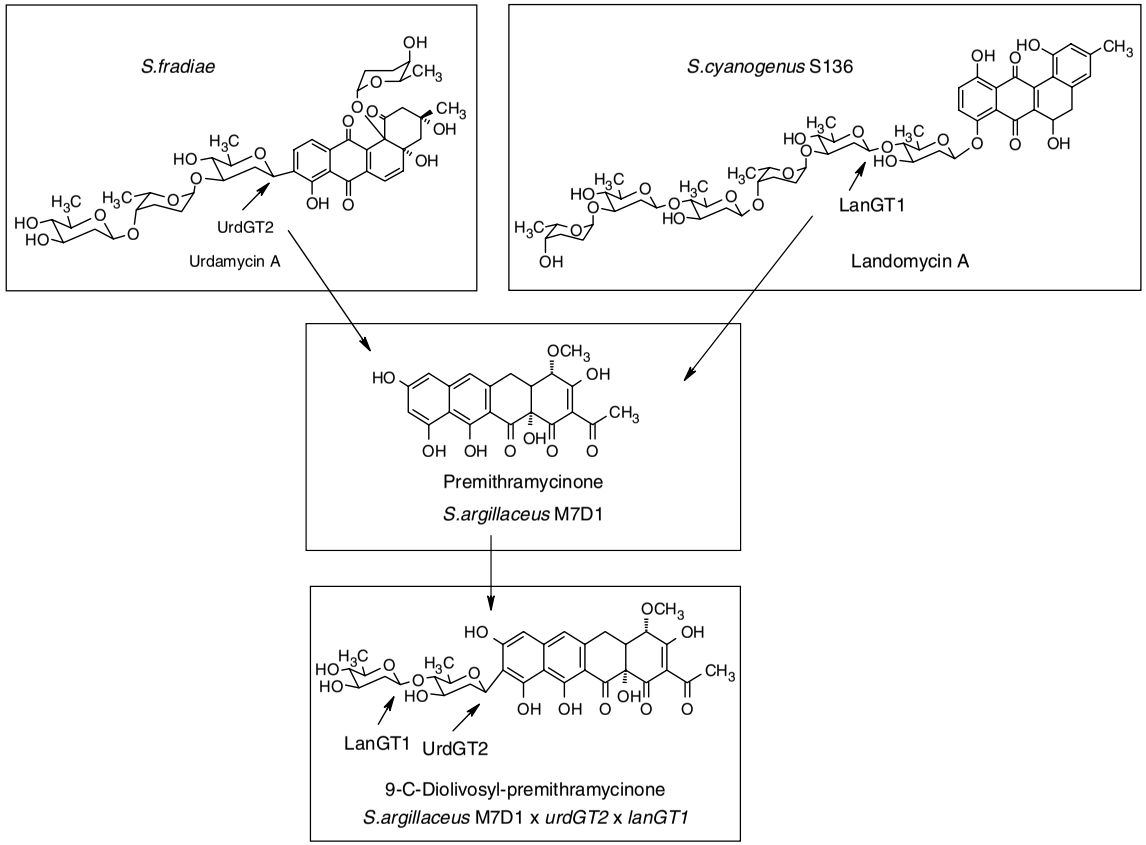

Fig. 4 Generation of a rationally designed hybrid product by coexpression of genes from three different organisms.

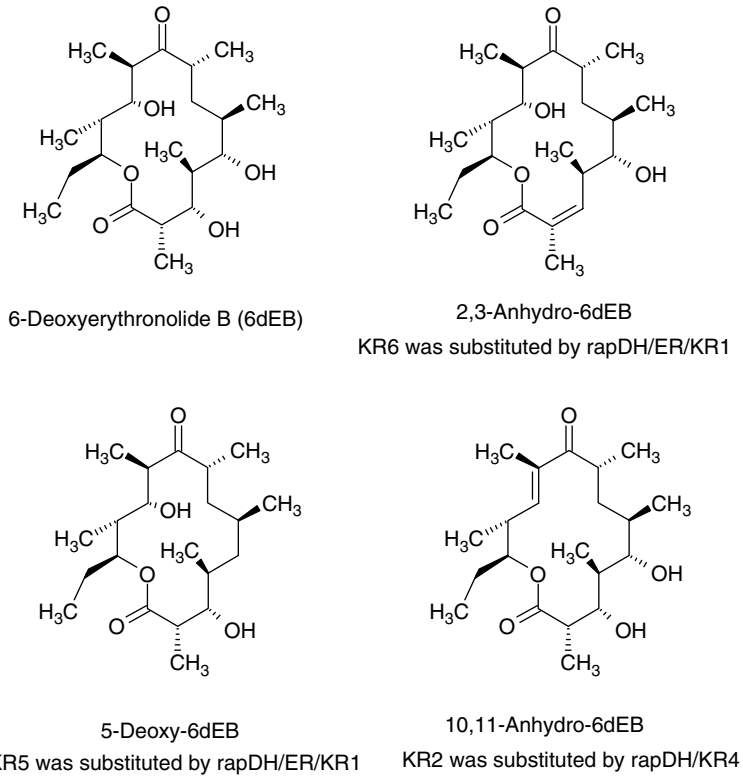

Fig. 5 Production of novel natural compounds by exchanging of modules of polyketide synthases.

and, in most cases, are expensive to dispose of. However, a still unsolved issue is how a novel active compound is dealt with by the host strain. Highly antimicrobial or cytotoxic agents that are not immediately and effectively detoxified by the host's intrinsic mechanisms will kill the host strain long before the compound is detected in a screen. Therefore, especially in case of antimicrobials, scientists run the risk of selecting for structures innocuous to pathogens, and truly combinatorial approaches suffer from limited sugar diversity as a second drawback since only those sugars are available for drug-lead diversification whose biosynthetic routes are understood and the genes involved cloned.

To make use of the possibilities microbial enzymes, particularly natural product glycosyltransferases, offer to pharmaceutical biotechnologists, the glycorandomization paradigm has been proposed and developed. Its two key reactions are the bioconversion of free sugars (natural or unnatural ones) via sugar phosphates into nucleotide-bound sugars as substrates for flexible glycosyltransferases.

The glycorandomization process starts with a library of chemically synthesized sugars, is therefore only limited by the available chemistry and includes, for example, halogenated, thio-, or azidosugars. Thus, the range of available sugars is extended far beyond what is possible

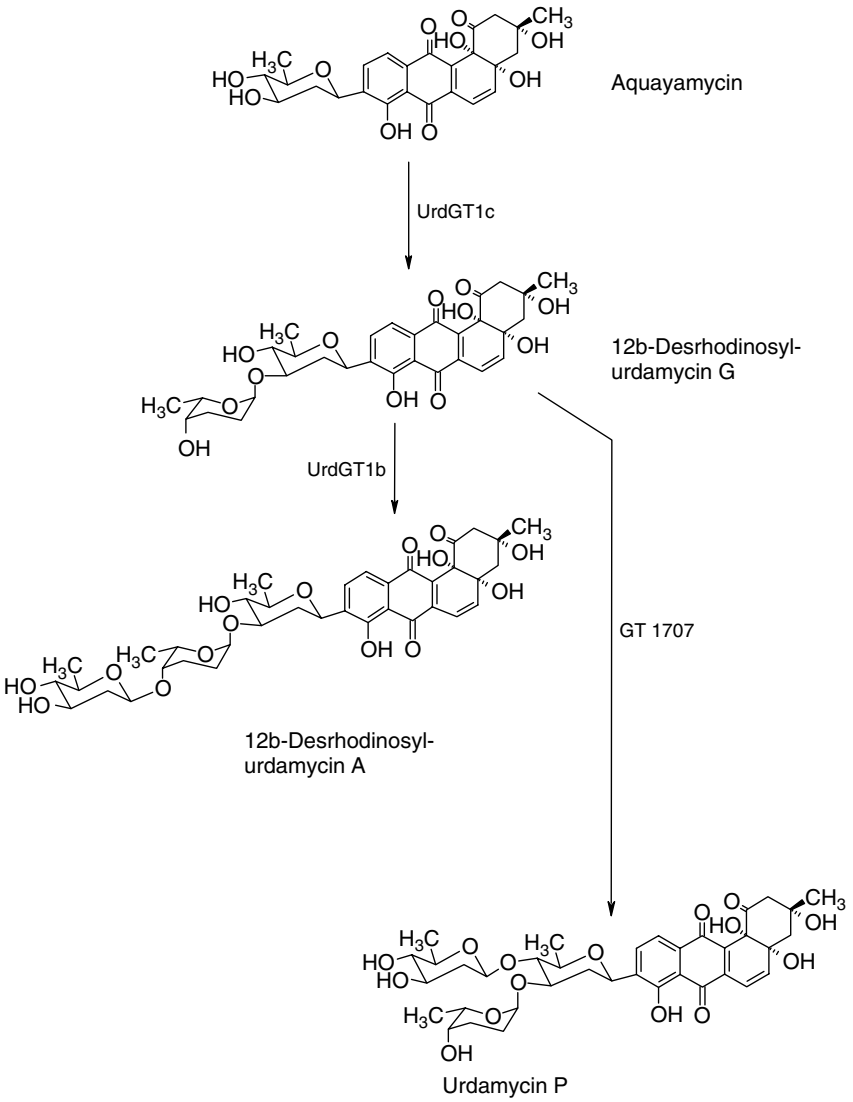

Fig. 6 Generation of urdamycin P by the expression of an "artificial" glycosyltransferase gene.

by biosynthetic pathways. These sugars are enzymatically converted to their anomeric phosphates during the kinase reaction, catalyzed by engineered *Escherichia coli* galactokinases and subsequently to dTDP- or UDP-derivatives by RmlA, the α-D-glucopyranosyl phosphate thymidylyltransferase from *Salmonella enterica* LT2. These enzymes display remarkable substrate flexibility after directed evolution or structure-based engineering. The RmlA-generated sugar nucleotides eventually

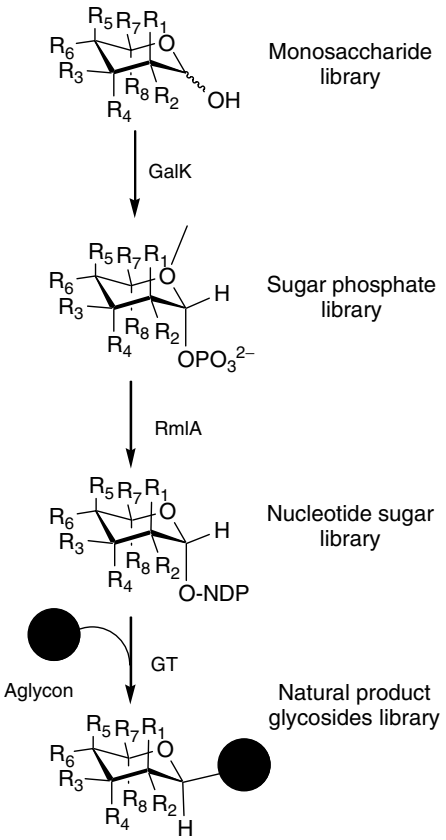

Fig. 7 Schematic of the glycorandomization strategy. Three enzymatic steps convert a library of free sugars into a library of natural product glycosides. GalK: galactokinase, RmlA: thymidylyltransferase, GT: glycosyltransferase, NDP: nucleosid diphosphate.

represent the sugar donor substrates for enzymatic glycosyltransfer.

Thus, glycorandomization involves only three enzymes (galactokinase, thymidylyltransferase, and a glycosyltransferase) to diversify natural product glycosides, thereby eliminating the need for large sets of biosynthetic genes (Fig. 7). If the sugar carries a reactive group, such as an azido-substituent, the glycorandomized molecules can be subjected to further chemical modifications under mild conditions thus creating an even more diverse pool of natural product derivatives.

Although being a very recent technique, glycorandomization has already demonstrated its versatility in its first application toward diversifying vancomycin and teicoplanin; nonribosomally generated sugar-decorated heptapeptides, which are in clinical use as antimicrobial drugs of last resort.

Combinatorial biosynthesis, and glycorandomization alike, are promising approaches to make use of the metabolic potential of prokaryotic cells and should promote drug development in the future. Potentially, glycorandomization can also be executed *in vivo* in a streptomycete host. In this case, the diverse intrinsic metabolites of Streptomycetes could be tapped as a rich source for drug backbone structures, the process could be scaled up easily, and expensive cosubstrates, for example, ATP, would be provided by the host.

1.4.5 **Novel Natural Compounds by Mutasynthesis**

The substrate flexibility of enzymes is also the basis for the ''mutasynthesis'' approach. During ''mutasynthesis,'' a microorganism containing a defined mutation in an important precursor biosynthesis gene of an interesting metabolite can be fed with alternative or even synthetic precursors. Consequently, derivatives of complex natural products are generated, which may not have been obtained by synthetic methods. This technology was successfully applied to generate the first fluorinated vancomycin-type antibiotics.

2 Saccharomyces Cerevisiae and Other Fungi in Biotech Production

Saccharomyces (Sa.) cerevisiae might be viewed to be one of the most important fungal organisms used in biotechnology. It has been used in the ''old biotechnology'' for baking and brewing since prehistory. Yeast genetics, yeast biochemistry, and, finally, yeast molecular biology have substantially contributed to the importance of *Sa. cerevisiae* also in the ''new biotechnology'' area.

Yeast is a unicellular organism, which, unlike more complex eukaryotes, is amenable to mass production. It can be grown on defined media, giving the investigator a complete control over environmental parameters. The availability of the complete genome sequence of *Sa. cerevisiae* opened the age of ''new biotechnology.'' In this chapter, we first review how genetic engineering of *Sa. cerevisiae* resulted in improved productivity and yield of important biotech products. Later, three examples of fungal natural products (or their derivatives) are described that have found their way into clinical use.

2.1 Generation of Engineered Strains of *Saccharomyces Cerevisiae* for the Production of Alcoholic Beverages

Alcohol fermentation is one of the most important processes of biotechnology. Generally, it is initiated by adding yeast to a carbon source and discontinues at a given alcohol concentration. The extension of the substrate range of *Sa. cerevisiae* is of major importance for the large-scale production of several metabolites. *Sa. cerevisiae* is not able to degrade starch and dextrin, since it does not produce starch-decomposing enzymes. Therefore, it is necessary to add starch-decomposing enzymes before fermentation. Attempts have been undertaken to use recombinant strains that contain the decomposing enzymes-encoding genes in order to avoid the preincubation process. The complete assimilation of starch (>98%) was accomplished by coexpression of the *sta2* gene of *Sa. diastaticus* encoding a glucoamylase, the *amy1* gene of *Bacillus amyloliquefaciens* encoding an α-amylase, and the *pulA* gene of *Klebsiella pneumoniae* encoding a pullulanase.

Further, genetically engineered strains have been developed, which are able to utilize lactose, melobiose, xylose, and other materials. A thermostable β-galactosidase encoded by *lacA* from *Aspergillus niger* was expressed in *Sa. cerevisiae*, enabling the strain to use lactose as carbon source. A melibiase-producing yeast was constructed by overexpressing the *melI* gene from another *Saccharomyces* strain. Moreover, after the coexpression of *xyl1* and *xyl2,* encoding a xylose reductase and xylitol dehydrogenase from *Pichia stipitis* along with the overexpressed xylulolkinase XKS1 from *Sa. cerevisiae*, xylose was converted to ethanol.

Especially in the large-scale production of beer, of highest significance is not ethanol production but a balanced flavor to obtain the desired taste. One unpleasant off-flavor compound is diacetyl, which is a nonenzymatically degraded product of α-acetolactate. Diacetyl is then enzymatically converted to acetoin and subsequently to 2,3-butanediol. The nonenzymatic-degradation step is very slow and requires long lager periods.

One way to avoid the off-flavor is to introduce an alternative route of degradation of α-acetolactate directly to acetoin.

α-Acetolactate decarboxylases from different organisms were successfully overexpressed in the beer-producer strains, accelerating the brewing process by diminishing the time of lagering by weeks.

Another interesting example is the expression of a β-glucanase of *Bacillus subtilis* in yeast. β-Glucans, the highly viscous side products during fermentation, impede beer filtration, which is still an important separation technique in the brewing industry. The presence of β-glucanase during fermentation did not affect the beer quality and taste but improved the filtration process.

2.2 Generation of Engineered Strains of *Saccharomyces Cerevisiae* for Lactic Acid, Xylitol, and Strictosidine Production

Several lactate dehydrogenases (LDHs) were expressed in *Sa. cerevisiae* in order to produce lactic acid. Most successful was the expression of a fungal (*Rhizopus oryzae*) lactate dehydrogenase (LDH). A recombinant strain accumulated approximately 40% more lactic acid with a final concentration of 38 g L^{-1} lactic acid and a yield of 0.44 g of lactic acid per gram of glucose. Xylitol is an attractive sweetener used in the food industry. Xylitol production in yeast was performed by the expression of *xyl1* of *P. stipitis*, encoding axylitosereductase.

A transgenic *Sa. cerevisiae* was constructed harboring the cDNAs that encodesstrictosidine synthase (STR) and strictosidine β-glucosidase (SGD) from the medicinal plant *Catharanthus roseus*. Both enzymes are involved in the biosynthesis of terpenoid indole alkaloids. The yeast culture was found to express high levels of both enzymes. Upon feeding of tryptamine and secologanin, this transgenic yeast culture produced high levels of strictosidine.

2.3 The Use of Fungi in the Production of Statins, Cyclosporin, and ß-Lactam Antibiotics

Statins are the secondary metabolites of a number of different filamentous fungi. Their medical importance and commercial value stem from their ability to inhibit the enzyme (3*S*)-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase. Since this enzyme catalyzes a key step in the endogenous cholesterol biosynthetic pathway, statins have become the widely used antihypercholesterolemic drugs. Along with some synthetic statins, the most prominent examples are lovastatin, mainly from *Aspergillus terreus*, and mevastatin produced by *Penicillium citrinum*, which was the first statin to be discovered.

Chemical modification, for example, hydroxylation, turned out to be rather unproductive during derivatization efforts. Therefore, biotransformation and biotechnological approaches have become the strategy of choice relatively early. For example, a two-step fermentation/biotransformation process has been established for the clinically important pravastatin: Its direct precursor mevastatin is obtained out of a culture in the first step and is then subjected to biotransformation, for example, by *Streptomyces carbophilus* to complete pravastatin biosynthesis by introducing a hydroxyl group at C-6. Later, improved *Aspergillus* and *Monascus* strains for direct pravastatin production were described. Pioneering work on the genetics and enzymology underlying lovastatin biosynthesis was published in 1999, paving the way for

the generation of novel derivatives. Recently, an approach termed *association analysis* was developed to further improve statin producers. The interrelationship between secondary metabolite production levels and genome-wide gene expression was profiled for a minilibrary of *Aspergillus terreus* strains engineered to express either wild type or engineered genes that are part of the lovastatin cluster itself or implicated in secondary metabolite regulation. The authors found that multiple genes/proteins attributed to cellular processes as diverse as primary metabolism, secondary metabolism, carbohydrate utilization, sulfur assimilation, transport, proteolysis, and many more correlate with increased (or decreased) lovastatin production levels. This approach revealed multiple points from which to start engineering and may help manipulate statin-producing filamentous fungi for industrial purposes.

Cyclosporin A (INN: ciclosporin) is a cyclic, nonribosomally-synthesized undecapeptide from *Tolypocladium inflatum* (Fig. 2). Apart from its antifungal properties, it represents a potent immunosuppressive drug as it interferes with lymphokine production. Cyclosporin A has been introduced into clinical use to prevent allograft rejection after organ transplants.

The biosynthesis of cyclosporin A has been extensively investigated. A huge 45.8-kb open reading frame was identified as a putative gene coding for the cyclosporine synthetase, a multifunctional peptide synthetase. With a molecular mass of 1689 kDa, it represents one of nature's largest enzymes. Fungal peptide synthetases are somewhat different from their prokaryotic counterparts in that they usually consist of one huge single enzyme, as is the case for cyclosporin, whereas bacteria generally use multi-unit synthetases. Further, fungal peptides often include D-configured amino acids. However, these peptide synthetases do not harbor an epimerization domain. In the case of cyclosporin, an external alanin racemase responsible for supplying the synthetase with D-alanine has been purified and characterized. Even before the cyclosporin synthetase was characterized, it had become obvious that the biosynthetic pathway tolerates a number of substrate analogs. For example, D-alanine can be replaced by D-serine as was demonstrated by precursor-directed biosynthesis thereby leading to novel cyclosporin derivatives.

For enhanced scaled-up cyclosporin production, a modified sporulation/immobilization method has been proposed, increasing the cyclosporin yield up to tenfold, compared to suspended culture techniques. The immobilization of cells on celite carrier beads decreases the culture's viscosity and therefore increases the mass transfer. It is possible to run the fermentation continuously since the fungal spores can be trapped in the fermenter vessel to populate and germinate on freshly added beads.

Ever since penicillin was discovered and further developed into a drug for use in humans, there has hardly been a natural product that parallels its impact on medicine and pharmacy. Yet, penicillin is only one example of the β-lactam antibiotics class, along with other fungal (and streptomycete) secondary metabolites, for example, cephalosporin C from *Acremonium chrysogenum*. The commercial importance of penicillins and cephalosporins is evident from the worldwide annual sales for these compounds (including their semisynthetic derivatives), which is estimated to reach US$ 15 billion, and of that, US$ 4.8 billion derived from sales

in the United States. β-Lactam biosynthesis has been thoroughly investigated. In brief, a nonribosomal peptide synthetase assembles the building blocks, L-α-aminoadipic acid, L-valine (which is epimerized to D-valin), and L-cysteine, into a linear tripeptide, which is then cyclized to isopenicillin N (IPN) by the enzyme IPN synthase. The latter enzyme has been crystallized and, by elegant X-ray diffraction investigations, been used to support the notion that the bicyclic enzymatic product IPN is synthesized in a two-step process, with β-lactam formation preceding the closure of the thiazolidine ring. IPN represents the last common intermediate along the pathways toward penicillin and cephalosporins. While penicillin biosynthesis requires only side-chain modifications, the five-membered penicillin thiazolidine ring is expanded to a dihydrothiazine system on the route to cephalosporins. Gene clusters coding for the enzymatic machinery of β-lactam biosynthesis have been cloned from *Penicillium chrysogenum, A. nidulans* (Penicillins), and *Acremonium chrysogenum* (Cephalosporin C). Strain development, fermentation, recovery, and purification conditions for β-lactam producers have been subjected to optimization ever since commercial production started. For example, modern fed-batch fermentations yield penicillin titers exceeding 40 g L^{-1} (compared to less than 1 g L^{-1} in 1950). Penicillin G and V are produced in highly automated fermentation vessels with a capacity in the 100 to 400 000 L range. Although costs for energy and labor have increased, the advances in penicillin production techniques have led to a drastic decrease in bulk prices from ~US$300 per kg in the early 1950s to ~US$15 to 20 per kg today.

3 Plants in Biotech Production

From the very roots of humanity, plants have made a crucial contribution to our well being. Plant products have been used as food and as medicine. Even today, plants are an important source for the discovery of novel pharmacologically active compounds, though the recent competition from combinatorial chemistry and computational drug design has declined the interest. In recent years, gene technology has opened up exciting perspectives and offers tools not only to improve the existing properties of plants, such as the amount of bioactive compounds, but also to create transgenic plants with new properties. Facile transformation and cultivation not only make plants suitable for the production of secondary metabolites but also for recombinant proteins. Plants are capable of carrying out acetylation, phosphorylation, and glycosylation as well as other posttranslational protein modifications required for the biological activity of many eukaryotic proteins. This chapter gives some examples describing the use of plant cells in biotech production by which pharmaceuticals as well as functional and medicinal food are obtained. In this article, we restrict ourselves to a secondary metabolite plant in the low molecular-weight range.

3.1 Transgenic Plants as Functional Foods or Neutraceuticals

A few years ago, industry started the age of engineered functional food. Numerous examples such as the generation of golden rice, the production of healthy plant oils, and engineered plants with

Tab. 2 Examples of new properties in transgenic plants used as neutraceuticals.

Property	*Plant*
Resveratrol	Peanut
Increased amount of iron and its bioavailability by the reduction of phytic acid	Maize
Lactoferrin	Rice
Enriched ferritin leading to the binding of iron and consequently to its accumulation	Lettuce
Removal of bitter-tasting compounds (glycoalkaloids)	Potatoes

increased levels of essential vitamins and nutrients have been published (Table 2). Golden rice was engineered with two plant genes from *Narcissus pseudonarcissus* encoding a phytoene synthase and a lycopene ß-cyclase along with one bacterial gene from *Erwinia uredovora* encoding a phytoene desaturase to synthesize ß-carotene, a precursor of vitamin A. This was possible because the transformation of rice was well established and all carotinoid biosynthetic pathway genes had been identified. Despite these promising results, golden rice is not yet on the market. Further work aims to increase the provitamin A amount and to unify high-iron rice lines with provitamin A lines, as it is known that provitamin A potentially increases iron bioavailability.

Wheat is a further target in the area of engineered functional food. A gene encoding a stilbene synthase was expressed in rice that enabled wheat to produce resveratrol. This natural antioxidant possesses positive effects against the development of thrombosis and arteriosclerosis. Moreover, in its glycosidic form it enhances resistance to fungal pathogenes, which also occurs in transgenic plants.

The current health-related objective of plant seed engineering is to increase the content of "healthy fatty acids" and reduce "unhealthy fatty acids" in oilseed crops, such as soybean, oil palm, rape-seed, and sunflower. Genetic engineering was successful in reducing the levels of trans-unsaturated fatty acids and in reducing the ratio between omega-6 and omega-3 unsaturated fatty acids in some vegetable oils. Metabolic engineering also succeeded in increasing the vitamin E, vitamin C, and the lycopene content in plants, as well as the content of bioflavonoids, known for their antioxidant, anticancer, and estrogenic properties. In addition, human milk proteins like lactoferrin can now be expressed in plants. These proteins are believed to have a multitude of biological activities that benefit the newborn infant. Functional food selected and advertised for its high content of therapeutically active molecules is already offered in the shelves of supermarkets, leaving the determination of their true medical benefit to the consumer.

A further research area is the elimination of natural compounds from a plant to avoid severe side effects. As an example, peanut causes allergies due to several proteins. Researchers are now working on the generation of plants with reduced levels of these proteins.

3.2 Transgenic Plants and Plant Cell Culture as Bioreactors of Secondary Metabolites

Biotech methods are also used to increase the amount of pharmaceutically interesting compounds in plants. Leaves of *Atropa belladonna* contain high amounts of L-hyoscyamin, but negligible

contents of L-scopolamin due to the low activity of hyoscyamin-6ß-hydroxylase (H6H) in roots. H6H-cDNA was isolated from *Hyoscyamus niger*, cloned, and introduced in *A. belladonna* using *Agrobacterium tumefaciens*. Transgenic plants as well as the sexual descendents contain the transgene and accumulate up to 1% of L-scopolamin, but only traces of L-hyoscyamin (Table 3).

Another approach to produce biologically active secondary metabolites is the use of plant cell cultures. Plant cell cultures are advantageous in that they are not limited by environmental, ecological, or climatic conditions. Further, cells can proliferate at higher growth rates than whole plants in cultivation. As shown in Table 4, some metabolites in plant cell cultures have been reported to accumulate with a higher titer compared to those in the parent plants. Some industrial processes harness this potential, for example, for shikonin, ginseng, and paclitaxel production. Especially *Taxus* cell cultures are an interesting alternative to the isolation of paclitaxel from plantation- grown plants as the slow growth of *Taxus* species, the significant variation in taxoid content, and the costly purification of 10-deacetylbaccatin III from co-occurring taxoids are significantly limiting parameters. Using cell cultures, taxol production rates up to 23.4 mg L^{-1} per day with paclitaxel comprising 13 to 20% of the total taxoid fraction can now be achieved.

However, the use of plant cell cultures for the production of interesting

Tab. 3 Transgenic plants with selected improved production of secondary metabolites.

Compound	*Target protein*	*Gene donor*	*Gene recipient*

molecules has not gained acceptance in industry as yet. Usually, low productivity and high costs are the most important negative parameters. Nevertheless, research is still going on and is well described in the next article. Further application of plant-cell-suspension cultures are aimed at the production of ajmalicine, vinblastine, vincristine, podophyllotoxins, and camptothecin.

3.3 Transgenic Plants as Bioreactors of Recombinant Proteins

Nowadays, plants such as tobacco, potato, tomato, banana, legumes, and cereals as well as alfalfa, are used in molecular farming and have emerged as promising biopharming systems for production of pharmaceutical proteins, such as antibodies, vaccines, regulatory proteins, and enzymes (Table 5). The advantages offered by plants include low cost of cultivation, high biomass production, relatively fast protein synthesis, low operating costs, excellent scalability, eukaryotic posttranslational modifications, low risk of pathogenicity toward humans and endotoxins, and a relatively high protein expression level. Using transgenic plants as a host is highly attractive in that proteins can be administered in fruits and vegetables as a source of antigens for oral vaccination. Thus, potatoes expressing a synthetic *LT-B* gene, a labile toxin from *E. coli* were successfully used in a clinical study to examine an edible plant vaccine. Further, interesting vaccines that have been tested clinically are directed against viral diarrhea and hepatitis B. No plant-derived protein has still been developed to be used as a drug, but molecular farming has gained attention as plants can be turned into molecular medicine factories.

Recently, plant cells have also been considered to be an alternative host for the production of recombinant proteins since they are able to glycosylate proteins. Of the various systems used for

cultivation, such as hairy roots, immobilized cells, and free cell suspensions, the latter is regarded to be most suitable for large-scale applications. Full-size antibodies, antibody fragments, and fusion proteins can be expressed in transgenic plant–cell systems, such as *Nicotiana tabacum*, pea, wheat, and rice using shake-flask or fermentation cultures. Yet, these systems are still of low commercial importance as their productivity is not advantageous.

Keywords

AAA ATPases
A large subfamily of ATPases involved in separating and unfolding proteins. The six ATPases of the 19S regulatory complex are members of the AAA subfamily.

Aggresome
''Abnormal proteins'' – pericentrosomal accumulations of abnormal proteins that recruit chaperones and proteasomes.

Base
A nine-protein subcomponent of the 19S regulatory complex, containing six ATPases and three proteins that recognize ubiquitin or ubiquitin-like proteins.

Chaperone
Chaperones are proteins that assist in the folding of nascent proteins or the refolding of denatured proteins. The heat shock proteins such as hsap90 or hsp70 are prime examples.

COP9 Signalosome (Csn)
A protein complex containing a metalloisopeptidase that removes the ubiquitin-like protein NEDD8 from ubiquitin ligases. Each of the eight Csn subunits is evolutionarily related to the eight lid subunits in the 19S regulatory complex.

Degron
Short peptide motifs (or even single N-terminal amino acids) that confer rapid proteolysis on the polypeptides bearing them.

Ecm29
A proteasome-associated protein proposed to function either as a clamp holding the 19S RC to the 20S proteasome or as an adaptor that localizes the 26S proteasome to specific membrane compartments within cells.

Epoxomicin
A bacterial compound that is a specific inhibitor of the proteasome.

Hybrid Proteasome
A 20S proteasome with a 19S regulatory complex at one end and either PA28 or PA200 at the other.

Immunoproteasome
A 20S proteasome where each of the three constitutive catalytic subunits is replaced by an active subunit with altered substrate specificity. Immunoproteasomes are induced by immune cytokines and play a role in specifying epitopes presented by the Class-I immune pathway.

Lactacystin
A fungal metabolite that is a reasonably specific inhibitor of the proteasome's active sites.

Lid
An eight-protein subcomponent of the 19S regulatory complex, containing a metalloisopeptidase that removes ubiquitin chains from the substrate protein.

Metabolic Regulation
Metabolic regulation refers to the control of biological processes by changes in the concentration of metabolites or proteins or by changes in the activities of enzymes. Phosphorylation and ubiquitilation are widespread mechanisms for controlling enzyme activity.

PA28s (aka 11S REGs)
Donut shaped, heptameric protein complexes that bind the ends of the 20S proteasome and promote peptide entry to or efflux from its central proteolytic chamber.

PA200
A large nuclear protein that binds the ends of the 20S proteasome and is thought to play a role in DNA repair.

Proteasome Activators
Single polypeptide chains or small protein complexes that bind 20S proteasomes and stimulate peptide hydrolysis. To date, three have been discovered.

20S Proteasome
A cylindrical proteolytic particle composed of 28 subunits arranged as a stack of four heptameric rings. The enzyme's active sites face an internal chamber.

26S Proteasome
The only ATP-dependent protease discovered so far in the nuclear and cytosolic compartments of eukaryotic cells. The enzyme consists of one or two 19S regulatory complexes attached to the ends of the 20S proteasome.

19S Regulatory Complex (aka PA700)
A multisubunit particle containing six ATPases and eleven additional proteins that functions to bind, unfold, and translocate substrate proteins into the central proteolytic chamber of the 20S proteasome.

Ubiquitin
An exceptionally conserved 76-amino acid protein that is covalently attached to a wide variety of other eukaryotic proteins. Chains of ubiquitin attached to substrate proteins target them for destruction by the 26S proteasome.

VCP
A large hexameric ATPase that transfers some polyubiquitylated substrates to the 26S proteasome.

Velcade
A peptide boronic acid inhibitor of the proteasome used clinically to treat multiple myeloma.

The 20S proteasome was discovered in 1980 and the 26S proteasome six years later. Research over the past two decades has made it abundantly clear that the Ub-proteasome system is of central importance in eukaryotic cell physiology and medicine. At the cellular and biochemical levels, there are a number of unresolved problems. We need a crystal structure of the 19S RC, or better yet, the 26S proteasome, for they would surely provide an insight into the mechanism by which the 26S proteasome degrades its substrates. How the 26S proteasome itself is regulated and the extent to which proteasomal components vary among

tissues in higher eukaryotes are other important unresolved problems. As for the medical perspective, we need to know how many diseases will be found to arise because of defects in the ubiquitin–proteasome system. Hopefully, these problems will generate research on the UPS by some readers of this article.

1 Proteasomes – A Quick Summary

Proteasomes are multisubunit, cylindrical proteases found in eukaryotes, eubacteria, and archaebacteria. The proteasome's active sites face a central chamber buried within the cylindrical particle. Thus, the proteasome is an ideal intracellular protease because cellular proteins can only be degraded if they are actively transferred to the enzyme's central chamber. Eukaryotic proteasomes come in two sizes, the 20S proteasome and the considerably larger ATP-dependent 26S proteasome. The latter is formed when the 20S proteasome binds one or two multisubunit ATPase-containing particles known as *19S regulatory complexes*. The 26S proteasome is responsible for degrading ubiquitylated proteins and is therefore essential for a vast array of cellular processes including cell-cycle traverse, control of transcription, regulation of enzyme levels, and apoptosis. Being the key protease of the ubiquitin system, the 26S proteasome also impacts a number of human diseases, especially cancer, cachexia, and neurodegenerative diseases. Both 20S and 26S proteasomes can associate with other protein complexes. As their name implies, proteasome activators stimulate peptide hydrolysis and may serve to localize 20S and 26S proteasomes within cells. Hybrid proteasomes consist of the 20S proteasome with a 19S regulatory complex bound at one end and a proteasome activator at the other. Immunoproteasomes are formed when the catalytic subunits found in constitutive proteasomes are replaced by interferon-inducible subunits with different substrate specificities. Immunoproteasomes are found mainly in immune tissues where they play a role in Class-I antigen presentation.

2 The 20S Proteasome

2.1 Structure

We know the molecular anatomy of archaebacterial, yeast, and bovine proteasomes in great detail since high-resolution crystal structures have been determined for all three enzymes. The archaebacterial proteasome is composed of two kinds of subunits, called α and β. Each subunit forms heptameric rings that assemble into the 20S proteasome by stacking four deep on top of one another to form a "hollow" cylinder. Catalytically inactive α-rings form the ends of the cylinder, while proteolytic β-subunits occupy the two central rings. The quaternary structure of the 20S proteasome can therefore be described as $\alpha 7\beta 7\beta 7\alpha 7$. The active sites of the β-subunits face a large central chamber about the size of serum albumin (see Fig. 1). The α-rings seal off the central proteolytic chamber and two smaller antechambers from the external solvent. Archaebacterial proteasomes, with

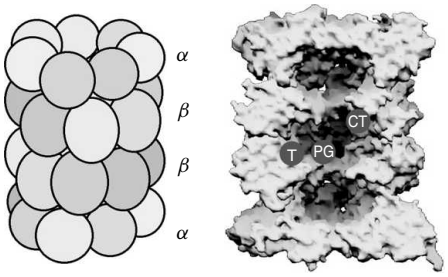

Fig. 1 20S Proteasomes. At the left is a schematic representation of a eukaryotic 20S proteasome. Different colors serve to emphasize the diversity of α and β subunits. At the right is a cutaway view of the yeast proteasome, showing the three internal cavities and the three protease activities: T (trypsin-like), PG (post glutamyl cleaving) and CT (chymotrypsin-like).

their fourteen identical β-subunits, preferentially hydrolyze the peptide bonds following hydrophobic amino acids and are therefore said to have chymotrypsin-like activity. Eukaryotic proteasomes maintain the overall structure of the archaebacterial enzyme, but they exhibit a more complicated subunit composition. There are seven different α-subunits and at least seven distinct β-subunits arranged in a precise order within their respective rings (see Fig. 1). Although current evidence indicates that only three of its seven β-subunits are catalytically active, the eukaryotic proteasome cleaves a wider range of peptide bonds containing, as it does, two copies each of trypsin-like, chymotrypsin-like, and post-glutamyl-hydrolyzing subunits. For this reason, it is capable of cleaving almost any peptide bond, having difficulty only with proline-X, glycine-X, and, to a lesser extent, with glutamine-X bonds.

2.2 Enzyme Mechanism and Proteasome Inhibitors

Whereas standard proteases use serine, cysteine, aspartate, or metals to cleave peptide bonds, the proteasome employs an unusual catalytic mechanism. N-terminal threonine residues are generated by self-removal of short peptide extensions from the active β-subunits, and they act as nucleophiles during peptide-bond hydrolysis. Given its unusual catalytic mechanism, it is not surprising that there are highly specific inhibitors of the proteasome. The fungal metabolite lactacystin and the bacterial product epoxomicin covalently modify the active-site threonines and inhibit the enzyme. Both compounds are commercially available; other inhibitors include vinylsulfones and various peptide aldehydes that are generally less specific. Recently, Velcade, a peptide boronate inhibitor of the proteasome, has been approved for the treatment of multiple myeloma.

2.3 Immunoproteasomes

Interferonγ is an immune cytokine that increases expression of a number of cellular components involved in Class-I antigen presentation. Among the IFNγ inducible components are three catalytically active β-subunits of the proteasome, called LMP2, LMP7, and MECL1. Each replaces its corresponding constitutive subunit, resulting in altered peptide-bond cleavage preferences of 20S immunoproteasomes. For example, immunoproteasomes exhibit much reduced cleavage after acidic residues and enhanced hydrolysis of peptide bonds following branch-chain amino acids such as isoleucine or valine. Class-I molecules preferentially bind peptides with hydrophobic or positive C-termini,

and proteasomes generate the vast majority of Class-I peptides. Hence, the observed β-subunit exchanges are well suited for producing peptides able to bind Class-I molecules.

3 The 26S Proteasome

3.1 The Ubiquitin–proteasome System

Bacteria can express as many as five ATP-dependent proteases. By contrast, the 26S proteasome is the only ATP-dependent protease discovered so far in the nuclear and cytosolic compartments of eukaryotic cells. Because the 20S proteasome's internal cavities are inaccessible to intact proteins, openings must be generated in the enzyme's outer surface for proteolysis to occur. A number of protein complexes have been found to bind the proteasome and stimulate peptide hydrolysis. (see Fig. 2). The most important of the proteasome-associated components is the 19S regulatory complex (RC), for it is a major part of the 26S ATP-dependent enzyme that degrades ubiquitin-tagged proteins in eukaryotic cells. Ubiquitin (Ub) is treated in a separate chapter of this Encyclopedia. Still, this important protein must be briefly covered since it plays a central role in substrate recognition by the 26S proteasome.

Ubiquitin is a small, evolutionarily conserved eukaryotic protein that can be attached to a wide variety of intracellular proteins, including itself. Although Ub serves nonproteolytic roles, such as histone modification or viral budding, the protein's major function is targeting proteins for destruction. To do so,

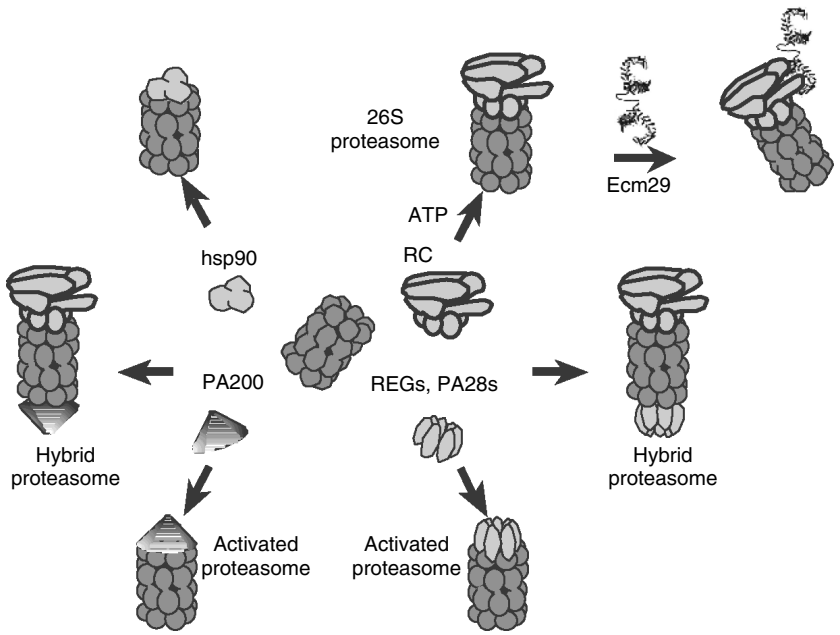

Fig. 2 Schematic representation of the 20S proteasome assembling with various activator proteins (RC, REGs, PA200) or with the chaperone hsp90, a protein that inhibits the enzyme.

the carboxyl terminus of ubiquitin is activated by an ATP-consuming enzyme (E1) and is transferred to one of several small carrier proteins (E2s) in the form of a reactive thiolester. The carboxyl terminus of an activated Ub then forms an isopeptide bond with lysine amino groups on proteolytic substrates (S) that have been selected by members of several large families of Ub ligases or E3s. Chains of Ub are formed, and the Ub-conjugated substrate is recognized by the 26S proteasome and degraded; Ub is recycled for use in further rounds of proteolysis (see Fig 3). It is important to note that ubiquitin contains seven lysine residues and polyUb chains formed via Lys6, Lys27, Lys29, Lys48, and Lys63 exist in nature. Lys29 and Lys48 chains form directly on proteolytic substrates and target them for destruction. Lys27 chains have been found on the cochaperone BAG1, and they target degradation of misfolded proteins bound by the Hsp70 chaperone to the 26S proteasome. Ub monomers linked to each other through Lys63 are involved in endocytosis and DNA repair, but not, apparently, in targeting proteins to the 26S proteasome.

3.2 Ultrastructure of the 26S Proteasome and Regulatory Complex

Electron micrographs (EMs) of purified 26S proteasomes reveal a dumbbell-shaped particle, approximately 40 nm in

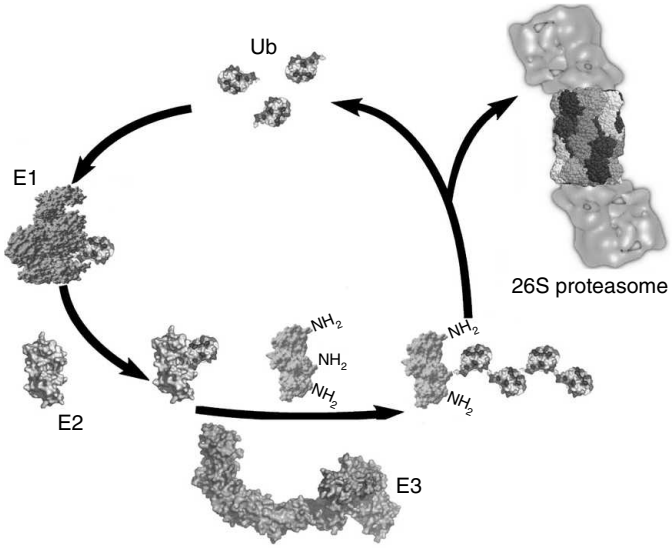

Fig. 3 Schematic representation of the ubiquitin-proteasome pathway. Ubiquitin molecules are activated by an E1 enzyme (shown in green at one-third scale) in an ATP-dependent reaction, transferred to a cysteine residue (yellow) on an E2 or Ub carrier protein and subsequently attached to amino groups (NH_2) on a substrate protein (lysozyme shown in purple) by an E3 or ubiquitin ligase, (the multicolored SCF complex). Note that chains of Ub are generated on the substrate, and these are recognized by the 26S proteasome depicted in the upper right at one-twentieth scale. (See color plate p. xxiv).

length, in which the central 20S proteasome cylinder is capped at one or both ends by asymmetric regulatory complexes looking much like Chinese dragonheads (see Fig 4). In doubly capped 26S proteasomes, the regulatory complexes face in opposite directions, indicating that contact between the proteasome's α-rings and the RC is highly specific. However, the contacts may not be especially tight since image analysis of Drosophila 26S proteasomes suggests movement of the RCs relative to the 20S proteasome. EM images of the 26S proteasome appear the same in all organisms, indicating that the overall architecture of the enzyme has been conserved in evolution. This conclusion is also supported by sequence conservation among RC subunits (see Sect. 3.4). A yeast mutant lacking the RC subunit Rpn10 contains a salt-labile RC that dissociates into two subcomplexes called the *lid* and the *base* (see Fig 4). The base contains 9 RC subunits, which include six ATPases described below in Sect. 3.4, the two largest RC subunits S1 and S2, as well as S5a; the lid contains the remaining RC subunits. Thus, the RC is composed of two subcomplexes separated on one side by a cavity, that is, the dragon's mouth. Ultrastructural studies have also been performed on the lid and on a related protein complex called the *COP9 signalosome*. Both particles lack obvious symmetry. Some particles exhibit a negative-stain-filled central groove; other classes of particles exhibit seven or eight lobes in a disc-like arrangement. Since both particles are composed of eight subunits, the lobes may represent individual subunits.

3.3 The 19S Regulatory Complex (RC)

The regulatory complex is also called the 19S cap, PA700, and the μ-particle. As its most common name suggests, the 19S regulatory complex is roughly the same size as the 20S proteasome. In fact, it is a more complicated protein assembly containing 17 or 18 different subunits, ranging in size from 25 to about 110 kDa. In animal cells, the subunits are designated S1 through S15. Homologs for each of these subunits are present in budding yeast where an alternate nomenclature has been adopted (see Table 1). Sequences for the 18 RC subunits permit their classification into a group of 6 ATPases and another group containing the 12 nonATPases.

3.4 ATPases of the RC

The six ATPases belong to the rather large family of AAA ATPases (for ATPases

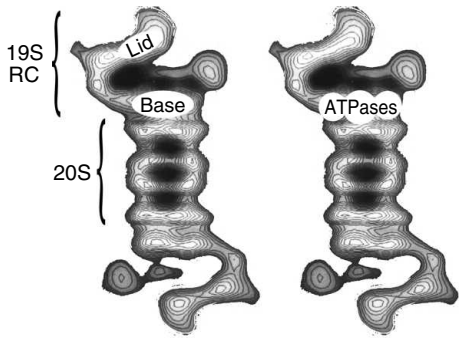

Fig. 4 Electron microscopic reconstructions of the 26S proteasome. Two images of negatively stained, doubly capped 26S proteasomes are presented to illustrate the positions of the 19S RC lid and base subcomplexes and to identify the most probable location of the RC ATPases.

Associated with a variety of cellular Activities) whose members include the motor protein dynein, the membrane fusion factor NSF, and the chaperone VCP/Cdc48. The six ATPases, denoted S4, S6, S6′, S7, S8, and S10b in mammals, are about 400 amino acids in length and homologous to one another. On the basis of their sequences, one can distinguish three major regions: (1) a central nucleotide binding domain of about 200 amino acids, which is roughly 60% identical among members of the RC subfamily; (2) the C-terminal region, approximately 100 amino acids in length and with a lesser, though significant, degree of conservation (~40%); and (3) a highly divergent N-terminal region (<20% identity) around 120 amino acids in length; this region contains heptad repeats characteristic of coiled-coil proteins. Despite sequence differences among RC ATPases within an organism, each ATPase has been conserved during evolution with specific subunits being almost 75% identical between yeast and humans. The high degree of conservation encompasses the entire sequence, making it likely that even the divergent N-terminal regions play an important role in RC function. Conceivably, they are used to select substrates for degradation by the 26S proteasome. The ''helix-shuffle'' hypothesis proposes that the N-terminal coiled-coils of S4 subfamily ATPases bind unassembled substrate proteins such as fos or jun through the latter's unpaired leucine zippers. Alternatively, the variable N-terminal regions in the RC ATPases may be involved in the assembly of the RC by promoting the specific placement of the ATPase subunits within the complex. In this regard, the six ATPases associate with one another in highly specific pairs: S4 binds S7, S6 binds S8, and S6′ binds to S10b. Moreover, the N-terminal regions of RC ATPases are required for

partner-specific binding. Staining patterns of two-dimensional gels show the six RC ATPases to be present at comparable levels and the affinity capture of yeast 26S proteasomes indicate the presence one copy of each in the regulatory complex. Mutational analysis in yeast demonstrates that the ATPases are not functionally redundant since mutation of yeast S4 has a particularly profound effect on peptide hydrolysis. It is probable that the ATPases form a hexameric ring like other members of the AAA family of ATPases such as NSF or VCP/Cdc48. But this assumption has not been experimentally verified. Finally, it is quite likely that the ATPases directly bind the α-ring of the 20S proteasome. Evidence favoring this arrangement comes from chemical cross-linking experiments and the presence of the ATPases in the base subcomplex of the yeast 26S proteasome.

3.5 The non-ATPase Subunits

Whereas the six RC ATPases are homologous and relatively uniform in size, the nonATPases are heterogeneous in size and sequence. Nonetheless, they can be grouped on the basis of their location, for example, lid versus base, on the presence or absence of certain sequence motifs, for example, PCI and MPN domains, and on their affinity for Ub chains or Ub-like proteins. Eight RC subunits are found in the lid subcomplex. One of these subunits (S13) is a metalloisopeptidase that removes Ub chains from the tagged substrate prior to its translocation into the proteasome for degradation. Each of the eight lid subunits is homologous to a subunit in a separate protein complex called the COP9 signalosome. Six of the eight lid subunits contain PCI domains, stretches of about 200 residues so named from their occurrence in Proteasome, COP9 signalosome, and the eukaryotic Initiation factor 3 subunits. The PCI domains are thought to mediate subunit–subunit interactions. Two lid subunits contain 140 amino acid long MPN domains (Mpr1p and Pad1p N-terminal regions), with one of these subunits being the S13 isopeptidase. Although several models have been proposed from 2-hybrid screens of lid and COP9-signalosome subunits, the arrangement of the eight subunits within the lid subcomplex is not known with certainty. S13 stands out because it exhibits isopeptidase activity. Functions of the remaining seven lid subunits have not been discovered, although two lid subunits, S3 and S9, are critical for the degradation of specific substrates. The presence of the S13 isopeptidase in the lid explains why the lid is necessary for degradation of ubiquitylated proteins, even though the RC–base complex supports the ATP-dependent degradation of some small nonubiquitylated proteins. Interestingly, the COP9-signalosome also exhibits isopeptidase activity that removes the ubiquitin-like protein, NEDD8, from certain ubiquitin ligases.

In addition to the six ATPases, the base subcomplex contains the two largest RC subunits (S1, S2) and a smaller subunit called S5a. Besides their common location, these three subunits share the property of binding polyUb chains or Ub-like domains. S5a binds polyubiquitin chains even after it has been transferred from SDS-PAGE gels, and it displays many features that match polyubiquitin recognition by the 26S proteasome. However, S5a cannot be the only ubiquitin recognition component in the 26S proteasome because deletion of the gene-encoding yeast S5a has only a modest impact on proteolysis. This strongly suggests that there

are other ubiquitin recognition components in the RC, with S1 and S2 being prime candidates. S1 and S2 display significant homology to each other, and both can be modeled as α-helical toroids. They have been shown to bind the ubiquitin-like domains of RAD23 and Dsk2, adapter proteins that target ubiquitylated proteins to the 26S proteasome. It has also been found that the S6′ ATPase can be cross-linked to Ub. Currently, then it appears that the RC contains three, or possibly four, subunits able to recognize Ub or Ub-like proteins. As discussed below, there are other ways in which the RC can select proteins for destruction.

3.6 Biochemical Properties of the Regulatory Complex

3.6.1 Nucleotide Hydrolysis

Both the 26S proteasome and the regulatory complex hydrolyze all four nucleotide triphosphates, with ATP and CTP preferred over GTP and UTP. K_ms for hydrolysis by the 26S proteasome are two- to fivefold lower for each nucleotide and virtually identical to the Kms required for Ub-conjugate degradation. Although ATP hydrolysis is required for conjugate degradation, the two processes are not strictly coupled. Complete inhibition of the peptidase activity of the 26S proteasome by calpain inhibitor I has little effect on the ATPase activity of the enzyme. The nucleotidase activities of the RC and the 26S proteasome closely resemble those of *Escherichia coli* Lon protease, which is composed of identical subunits that possess both proteolytic and nucleotidase activities in the same polypeptide chain. Like the regulatory complex and 26S proteasome, Lon hydrolyzes all four ribonucleotide triphosphates, but not ADP or AMP.

3.6.2 Chaperone-like Activity

AAA nucleotidases share the common property of altering the conformation or association state of proteins. So, it is not surprising that the RC has been shown to prevent aggregation of several denatured proteins including citrate synthase and ribonuclease A. The chaperone activity of the RC may explain why the RC plays a role in DNA repair even in the absence of an attached 20S proteasome.

3.6.3 Proteasome Activation

The 20S proteasome is a latent protease because of the barrier imposed by the α-subunit rings on peptide entry. Consequently, a readily measured activity of the RC is activation of fluorogenic peptide hydrolysis by the 20S proteasome. The extent of activation is generally found to be in the range 3- to 20-fold. Activation is relatively uniform for all three proteasome catalytic subunits and presumably reflects opening by the attached RC of a channel, leading to the proteasome's central chamber.

3.6.4 Ubiquitin Isopeptide Hydrolysis

The channel through the proteasome α-ring into the central chamber measures 1.3 nm in diameter, a size too small to permit passage of a folded protein even as small as ubiquitin. This consideration coupled with the fact that Ub is recycled intact upon substrate degradation requires an enzyme to remove the polyUb chain prior to or concomitant with proteolysis. Several isopeptidases that remove Ub from substrates has been found associated with the 26S proteasome. Of these, S13 is an integral component of the enzyme. S13 is a metalloisopeptidase stimulated by nucleotides and is active only in the fully assembled 26S proteasome. Thus, it is not

strictly correct to list isopeptidase activity as a property of the RC.

3.6.5 Substrate Recognition

It is clear that the RC plays a predominant role in selecting proteins for degradation. This important topic is covered in Sect. 5 in the context of substrate recognition by both 20S and 26S proteasomes.

4 Proteasome Biogenesis

4.1 Subunit Synthesis

The synthesis of proteasome subunits is markedly affected by proteasome function. For example, inhibition of proteasome activity by lactacystin induces coordinate expression of both RC and 20S proteasome subunits. Similarly, impaired synthesis of a given RC subunit results in overexpression of all RC subunits. Proteasome subunit synthesis in yeast is controlled by Rpn4p, a short-lived positive transcription factor that binds PACE elements upstream of proteasome genes. Rpn4p is a substrate of the 26S proteasome, suggesting that the transcription factor functions in a feedback loop in which proteasome activity limits its concentration, thereby regulating proteasome levels. To date, an Rpn4-like factor has not been identified in higher eukaryotes; however, the presence of such a factor could explain why proteasome inhibition results in higher expression of proteasome subunits in mammalian and *Drosophila* cells.

4.2 Biogenesis of the 20S Proteasome

Proteasome β-subunits are synthesized with N-terminal extensions, and they are inactive because a free N-terminal threonine is required for peptide-bond hydrolysis. The precursor β-subunits assemble with α-subunits to form half proteasomes composed of one α-and one β-ring. These two ring intermediates dimerize to form the 20S particle, and the N-terminal extensions are removed, thereby generating a new unblocked N-terminal threonine in the catalytically active β-subunits. A small accessory protein called Ump1 in yeast and POMP or proteassemblin in mammalian cells assists in the final assembly of the 20S proteasome. Interestingly, Ump1/POMP is apparently trapped in the proteasome's central chamber and degraded upon maturation of the enzyme.

4.3 Biogenesis of the RC

Assembly pathways for the RC are virtually unknown. As mentioned above, the ATPases interact with one another and complexes containing all six S4 subfamily members have been observed following *in vitro* synthesis. Impaired synthesis of a lid subunit can result in the absence of the entire lid, so presumably, lid and base subcomplexes assemble independently and associate in the final stages of RC formation cells. *In vivo*, 26S proteasomes assemble from preformed regulatory complexes and 20S proteasomes.

4.4 Posttranslational Modification of Proteasome Subunits

Proteasome and RC subunits are subjected to a variety of posttranslational modifications including phosphorylation, acetylation, and even myristoylation in the case of the RC ATPase S4. In yeast, all seven α-subunits as well as two

β-subunits are acetylated. Since acetylation of the N-terminal threonine in an active β-subunit would poison catalysis, it has been suggested that the propeptide extensions function to prevent acetylation. Three members of the S4 ATPase subfamily (S4, S6, and S10b) and two 20S α-subunits (C8 and C9) are known to be phosphorylated. Phosphorylation appears to be particularly important for 26S proteasome assembly since the kinase inhibitor staurosporine reduces 26S proteasome levels in mouse lymphoma cells.

4.5 Biogenesis of the 26S Proteasome

The RC and 20S proteasome associate to form the 26S proteasome in the presence of ATP. Comparison of the cross-linking patterns of RC and assembled 26S proteasomes indicates that this association is accompanied by subunit rearrangement. In yeast, two proteins play a special role in 26S proteasome assembly or stability. Nob1p is a nuclear protein required for biogenesis of the 26S proteasome. It is degraded following assembly of the 26S enzyme, suffering the same fate as Ump1 does following 20S maturation. The molecular chaperone Hsp90 also plays a role in the assembly and maintenance of yeast 26S proteasomes since functional loss of Hsp90 results in 26S proteasome dissociation.

5 Substrate Recognition by Proteasomes

5.1 Degradation Signals (Degrons)

One of the major insights of twentieth century cell biology was the recognition that proteins possess built-in signals, targeting them to specific locations within cells. Selective proteolysis can be considered to be targeting out of existence, and a number of short peptide motifs have been discovered to confer rapid proteolysis on their bearers. These include PEST sequences, destruction boxes, KEN boxes, and even the N-terminal amino acid. These motifs are recognized by one or more ubiquitin ligases that mark the substrate protein by addition of a polyUb chain. However, some proteins are degraded by the 26S proteasome without prior marking by Ub. Denatured proteins are also selectively degraded by both 26S and 20S proteasomes. It is not clear what features of denatured proteins are recognized by proteasomes or by components of the Ub proteolytic system.

5.2 Ubiquitin-dependent Recognition of Substrates

Most well-characterized substrates of the 26S proteasome are ubiquitylated proteins, so our discussion starts with them. Efficient proteolysis of ubiquitylated proteins by the 26S proteasome requires a chain containing at least four Ub monomers. This matches well with the Ub-binding characteristics of the RC subunit S5a. It also selectively binds ubiquitin polymers composed of four or more ubiquitin moieties and exhibits increased affinity for longer chains. In addition, binding to S5a is impaired by mutations in ubiquitin that allow chain formation but reduce the targeting competence of the chains. These properties and the fact that denatured S5a can readily regain affinity for polyUb suggest that multiple, short sequences within S5a form ''loops'' that are able to bind ''grooves'' in the polyubiquitin

chain. S5a molecules from a number of higher eukaryotes contain two repeated motifs that are independent polyubiquitin binding sites. Each motif is approximately 30-residues long and is characterized by five hydrophobic residues that consist of alternating large and small hydrophobic residues, for example, leu-ala-leu-ala-leu. Similar motifs have been found in other proteins of the ubiquitin system and are now called UIMs, for Ubiquitin Interacting Motifs. Because a hydrophobic patch on the surface of ubiquitin is critical for substrate targeting, current models envision direct hydrophobic interaction between the UIMs in S5a and the hydrophobic patches on ubiquitin molecules in polyUb chains.

Whereas S5a provides for direct recognition of polyubiquitylated substrates, a second mechanism involves adaptor proteins possessing both a UbL (a Ubiquitin-like domain) and one or more UbA domains (Ubiquitin-associated domains are polyUb binding domains found in several proteins of the Ub system). The adaptor proteins include RAD23 and Dsk2 in yeast and recruit substrates to the 26S proteasome through UbL binding to 26S proteasome subunits, while the UbA domain binds substrate-tethered Ub chains. In yeast, the RC subunits S1 and S2 serve as UbL binding components; in mammals, S5a also serves this purpose.

The cochaperone BAG1 illustrates a third way in which polyUb can target substrate proteins to the 26S proteasome. In this case, the substrate is not polyubiquitylated; rather, it is bound to the chaperone Hsp70. A polyUb chain, linked through Lys27, is attached to the Hsp70-associated cochaperone BAG1. Apparently, the Lys27 chain promotes association of the chaperone–substrate complex with the 26S proteasome, after which the substrate is degraded while BAG1, Hsp70, and ubiquitin are recycled. Direct interaction between E3 ubiquitin ligases and RC subunits can also deliver ubiquitylated substrates to the protease. The yeast E3 UFD4 binds RC ATPases, and UFD4-mediated delivery of substrates bypasses the requirement for S5a. In what appears to be a similar delivery system, the mammalian E3 Parkin uses a UbL to bind the 26S proteasome. Mutational analyses in yeast have shown that whereas deletion of either S5a or Rad23 has mild impact on proteolysis, loss of both proteins produces a severe phenotype. Yeast lacking S5a, RAD23, and Dsk2 are not viable, indicating that direct delivery by E3s cannot compensate for the absence of all three proteins.

5.3 Substrate Selection Independent of Ubiquitin

The 26S proteasome also degrades nonubiquitylated proteins. The short-lived enzymeornithine decarboxylase (ODC) and the cell-cycle regulator p21Cip provide well-documented examples of Ub-independent proteolysis by the 26S enzyme. ODC degradation is stimulated by a protein called *antizyme* that binds to both ODC and the 26S proteasome. Antizyme functions as an adapter much like RAD23 and Dsk2 except that polyUb chains are not involved, although interestingly, free Ub chains compete with antizyme–ODC for degradation. p21Cip is also degraded in a nonUb-dependent reaction. This was clearly demonstrated by substitution of arginines for all the lysine residues in p21Cip, thereby preventing ubiquitylation of p21Cip. The lysine-less protein was still degraded in human fibroblasts by the proteasome. The C-terminal region of p21Cip binds to the proteasome α-subunit C8,

and in vitro p21Cip is degraded by the 20S proteasome alone. Direct binding of p21Cip to the 20S proteasome may open a channel through the α-ring, allowing the loosely structured protein to enter the central chamber. c-Jun, ''aged'' calmodulin, troponin C, and p53 are other proteins that can be degraded by the 26S proteasome absent marking by Ub. The destruction of p53 and p21Cip can proceed by both Ub-dependent and Ub-independent pathways. Other 20S proteasome substrates, *in vitro* at least, include oxidized proteins, small denatured proteins, and loosely folded proteins such as casein. Whether the 20S proteasome degrades proteins within cells is an unresolved problem.

6
Proteolysis by the 26S Proteasome – Mechanism

6.1
Contribution of Chaperones to Proteasome-mediated Degradation

Chaperones are connected to proteasomes in at least four ways. First, chaperones can deliver substrates to the proteasome as described above for the cochaperone BAG1. In a similar fashion, the chaperone VCP/Cdc48 is required for the degradation of several Ub pathway substrates. VCP is a member of the AAA family of ATPases. The large hexameric ATPase appears to function as a protein separase able to remove ubiquitylated monomers from multisubunit complexes. In some cases, the liberated proteins are degraded by the 26S proteasome; in other cases, the separated proteins may change their intracellular location. The proteasome also degrades endoplasmic-reticulum membrane proteins. If these ER membrane proteins possess a large cytoplasmic domain, their proteasomal degradation can require Hsps 40, 70, and 90 as well as VCP. Hsp90 is required to assemble and stabilize the yeast 26S proteasome, providing a third connection between chaperones and proteasomes. Hsp90 is also able to bind and suppress peptide hydrolysis by the 20S proteasome. Finally, both chaperones and proteasomes are induced by the accumulation of denatured proteins within eukaryotic cells.

6.2
Presumed Mechanism

Proteolysis of ubiquitylated proteins by the 26S proteasome can be thought to be consisting of seven steps: (1) chaperone-mediated substrate presentation; (2) substrate association with RC subunits; (3) substrate unfolding; (4) detachment of polyUb from the substrate; (5) translocation of the substrate into the 20S proteasome central chamber, (6) peptide-bond cleavage; and (7) release of peptide products as well as polyUb (see Fig 5). Step 1 is optional, depending on the substrate, and in principle, steps 3 and 4 could occur in either order. Step 4 is unnecessary for substrates like ODC that are not ubiquitylated. The other steps almost have to occur as presented. Although it is easy to conceptualize the reaction sequence, few experimental findings bear directly on any of the proposed subreactions, and virtually nothing is known about molecular movements within the 26S proteasome. It has been shown that steps 6 and 7 are not required for sequestration of ODC by the 26S proteasome. But which RC subunits actually recognize ODC–antizyme complexes has not been discovered. For ubiquitylated substrates, it is very likely

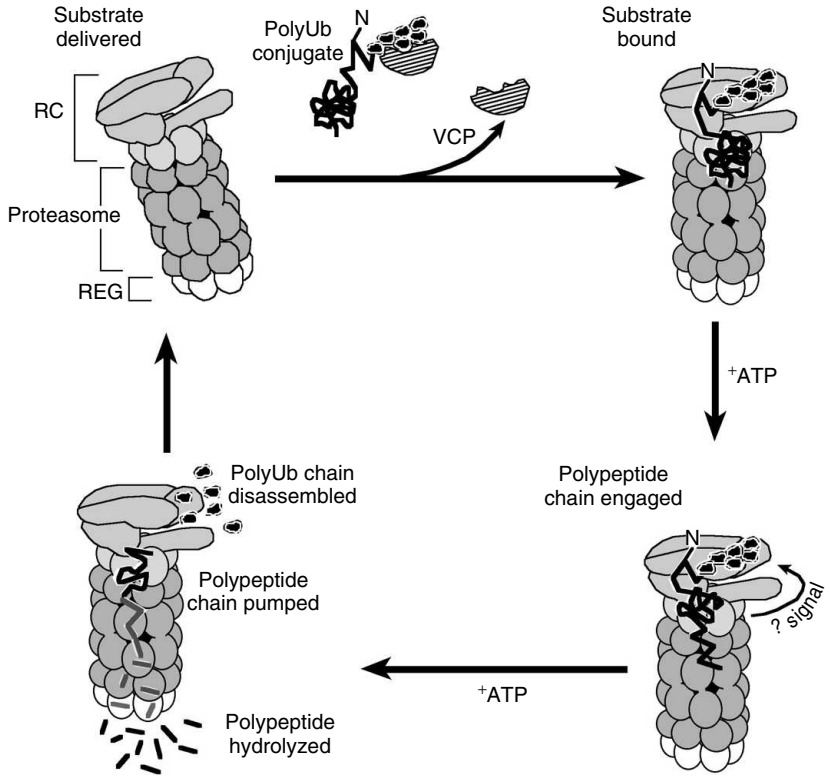

Fig. 5 Hypothetical reaction cycle for the 26S proteasome. A polyubiquitylated substrate is delivered to the 26S proteasome possibly by chaperones such as VCP (step 1). Substrate is bound by polyubiquitin-recognition components of the RC until the polypeptide chain is engaged by the ATPases (step 2). As the polypeptide chain is unfolded and pumped down the central pore of the proteasome, a signal is conveyed to the metalloisopeptidase to remove the polyUb chain (step 3). The unfolded polypeptide is eventually degraded within the inner chamber of the proteasome (step 4) and peptide fragments exit the enzyme.

that S1, S2, and S5a are recognition components, but this is not certain. Even if they are, we do not know whether they recognize just polyUb or polyUb and portions of the substrate. Translocation is thought to proceed by the six ATPases threading the polypeptide through a channel in the 20S proteasome's α-ring, but the possibility that convulsive movements transfer substrate has not been ruled out. It is also thought that the RC ATPases processively unravel substrates from degradation signals within the polypeptide chain and are able to ''pump'' the polypeptide chain in either N-terminal to C-terminal or the opposite direction. The ATPases may even be capable of transferring loops into the 20S enzyme. One thing that is certain is that the peptide fragments generated in the central chamber are generally 5 to 10 residues in length, but fragments as long as 35 amino acids can be present. How these fragments exit the central chamber is not known. Clearly, there is much to be discovered about the internal workings of the 26S proteasome.

6.3
Processing by the 26S Proteasome

In some cases, the 26S proteasome partially degrades the substrate protein releasing processed functional domains. The best-studied example of processing involves the transcriptional activator NFκB. The C-terminal half of a 105-kDa precursor is degraded by the 26S proteasome to yield a 50-kDa N-terminal domain that is the active transcription component. A glycine-rich stretch of amino acids at the C-terminal boundary of p50 is an important factor in limiting proteolysis. It is possible that polypeptide translocation by the RC starts at the glycine-rich region and proceeds in only one direction because of the presence of the tightly folded N-terminal domain. Or the RC may start translocation at the C-terminus and stop when the ATPases encounter the glycine-rich region. Another example of partial processing involves SPT23, a yeast protein embedded in the endoplasmic-reticulum membrane. SPT23 controls unsaturated fatty acid levels and membrane fluidity regulates 26S proteasomal generation of a freely diffusible transcription factor from the SPT23 precursor. Partial processing may be a more widespread regulatory mechanism than is currently thought.

7
Proteasome Activators

In addition to the RC, there are two protein complexes, REG$\alpha\beta$ and REGγ, and a single polypeptide chain, PA200, that bind the 20S proteasome and stimulate peptide, but not protein, degradation (see Fig. 2). Like the RC, proteasome activators bind the ends of the 20S proteasome, and importantly, they can form mixed or hybrid 26S proteasomes in which one end of the 20S proteasome is associated with a 19S RC and the other is bound to a proteasome activator. This latter property raises the possibility that proteasome activators serve to localize the 26S proteasome within eukaryotic cells.

7.1
REGs or PA28s

There are three distinct REG subunits called $\alpha\beta\gamma$. REG$\alpha\beta$ form donut-shaped hetero-heptamers found principally in the cytoplasm, whereas, REGγ forms a homo-heptamer located in the nucleus. REG$\alpha\beta$ are abundantly expressed in immune tissues while REGγ is highest in brain. The REGs also differ in their activation properties. REG$\alpha\beta$ activate all three proteasome active sites; REGγ only activates the trypsin-like subunit. There is reasonably solid evidence that REG$\alpha\beta$ play a role in Class-I antigen presentation, but we have no idea what REGγ does, especially since REGγ knockout mice have almost no phenotype. The crystal structure of REGα reveals that the seven subunits form a donut-shaped structure with a central aqueous channel, and the structure of a REG–proteasome complex provides important insight into the mechanism by which REGα activates the proteasome. The carboxyl tail on each REG subunit fits into a corresponding cavity on the α-ring of the proteasome and loops on the REG subunits cause N-terminal strands on several proteasome α-subunits to reorient upward into the aqueous channel of the REG heptamer. These movements open a continuous channel from the exterior solvent to the proteasome central chamber.

7.2 PA200

A new proteasome activator, called PA200, was recently purified from bovine testis. Human PA200 is a nuclear protein of 1843 amino acids that activates all three catalytic subunits, with preference for the PGPH active site. Homologs of PA200 are present in budding yeast, worms, and plants. A single chain of PA200 can bind each end of the proteasome, and when bound, PA200 molecules look like volcanoes in negatively stained EM images. Evidence from both yeast and mammals suggests that PA200 is involved in DNA repair.

7.3 Hybrid Proteasomes

As the α-rings at each end of the 20S proteasome are equivalent, the 20S proteasome is capable of binding two RCs, two PA28s, two PA200s, or combinations of these components. In fact, 20S proteasomes simultaneously bound to RC and PA28 or PA200 have been observed, and they are called *hybrid proteasomes*. In HeLa cells, hybrid proteasomes containing PA28 at one end and an RC at the other have been estimated to be twice as abundant as 26S proteasomes capped at both ends by 19S RCs. Hybrid 26S proteasomes containing PA200 appear to be much less abundant in HeLa cells.

7.4 ECM29

Another proteasome-associated protein, called ecm29, has been identified in several recent proteomic screens. Ecm29p is reported to stabilize the yeast 26S proteasome by clamping the RC to the 20S cylinder. However, in human culture cells, ecm29p is found predominately associated with the endoplasmic-reticulum Golgi intermediate compartment, a location suggesting a role in secretion rather than stability of 26S proteasome. Ecm29p clearly associates with 26S proteasomes; whether it activates proteasomal peptide hydrolysis is unknown.

8 Protein Inhibitors of the Proteasome

A number of proteins have been found to suppress proteolysis by the proteasome. One of these is PI31, another is the abundant cytosolic chaperone, Hsp90, and a third is a proline/arginine-rich 39-residue peptide called PR39. Both PI31 and Hsp90 may affect how the proteasome functions in Class-I antigen presentation. PI31 is a 30-kDa proline-rich protein that inhibits peptide hydrolysis by the 20S proteasome and can block activation by both RC and REG$\alpha\beta$. Although surveys of various cell lines show PI31 to be considerably less abundant than RC or REG$\alpha\beta$, when overexpressed, PI31 is reported to inhibit Class-I antigen presentation by interfering with the assembly of immunoproteasomes. A number of studies have shown that Hsp90 can bind the 20S proteasome and inhibit its chymotrypsin-like and PGPH activities. Interestingly, inhibition by Hsp90 is observed with constitutive but not with immunoproteasomes, a finding consistent with proposals that Hsp90 shuttles immunoproteasome-generated peptides to the endoplasmic reticulum for Class-I presentation. PR39 was originally isolated from bone marrow as a factor able to induce angiogenesis and inhibit inflammation. Two hybrid screens showed that PR39 binds the 20S

proteasome. Apparently, PR39 affects angiogenesis and inflammation by inhibiting respectively the degradation of HIF1 or IkBα, the latter being an inhibitor of NFkB. Finally, HIV's Tat protein inhibits the 20S proteasome's peptidase activity. Tat also competes with REG$\alpha\beta$ for proteasome binding, and by doing so, Tat can inhibit Class-I presentation of certain epitopes.

9 Physiological Aspects of Proteasomes

9.1 Tissue and Subcellular Distribution of Proteasomes

Proteasomes are found in all organs of higher eukaryotes, but the degree to which the composition of proteasomes and its activators varies among tissues is largely unexplored territory. Proteasomes are very abundant in testis since the organ contains almost fivefold more 20S subunits than skeletal muscle. At the cellular level, there are about 800 000 proteasomes in a HeLa cell and roughly 20 000 proteasomes in a yeast cell. At the subcellular level, 26S proteasomes are present in cytosol and nucleus where they appear to be freely diffusible. They are not found in the nucleolus or within membrane-bound organelles other than the nucleus. When large amounts of misfolded proteins are synthesized by a cell, the aberrant polypeptides often accumulate around the centrosome in what are called ''aggresomes.'' Under these conditions, 26S proteasomes, chaperones, and proteasome activators also redistribute to the aggresomes presumably to refold and/or degrade the misfolded polypeptides.

9.2 Physiological Importance

Deletion of yeast genes encoding 20S proteasome and 19S RC subunits is usually lethal, indicating that the 26S proteasome is required for eukaryotic cell viability. Known substrates of the 26S proteasome include transcription factors, cell-cycle regulators, protein kinases, and so on – essentially, most of the cell's important regulatory proteins. Surprisingly, even proteins secreted into the endoplasmic reticulum are returned to the cytosol for degradation by the 26S proteasome. Given the scope of its substrates, it is hardly surprising that the ubiquitin–proteasome system contributes to the regulation of a vast array of physiological processes, ranging in higher eukaryotes. Discussion of these fascinating regulatory mechanisms is beyond the scope of this article. A brief review of proteasomes and disease does, however, seem appropriate.

9.3 The Ubiquitin–proteasome System and Human Disease

As the central protease in the ubiquitin system, the 26S proteasome impacts a number of diseases, especially cancer, neurological diseases, and muscle wasting. Ubiquitin-mediated destruction of proteins driving cell division imparts directionality to the cell cycle. So it is not surprising that several cancers arise because of an impaired or overactive ubiquitin–proteasome system. VonHippel-Lindau (VHL) disease is a hereditary cancer syndrome, characterized by a wide range of malignant tumors. The protein defective in VHL is the substrate-recognition component of a Ub–ligase complex that targets

the transcription-component hypoxia-inducible factor 1 (HIF1) for destruction. HIF1 induces synthesis of VEGF, a growth factor important for angiogenesis, and many of the tumors in VHL involve the vasculature. The human papilloma virus oncoprotein E6 provides an example of an overactive Ub ligase causing cancer. E6 is a positive regulator of the Ub ligase that targets the tumor-suppressor protein p53 for degradation. Downregulation of p53 prevents apoptosis of HPV-transformed cells, thereby promoting malignancy. Angelman and Liddle's syndromes and juvenile-onset Parkinson's disease are three other human diseases involving E3 Ub ligases.

Impairment of the proteasome occurs in a number of neurodegenerative diseases, especially those characterized by formation of protein inclusions, such as Parkinson's and Huntington's diseases. In these diseases, proteasomes and ubiquitylated proteins accumulate at the inclusions. It is thought that sequestration and/or inhibition of proteasomes may impair normal protein turnover, eventually resulting in neuronal cell death.

The ubiquitin–proteasome system also plays a key role in cellular immunity. There is considerable evidence that proteasomes generate the majority of peptides presented on Class-I molecules to cytotoxic lymphocytes. Class-I antigen presentation is a major defense against viral infection, and viruses have devised a number of ways to prevent Class-I molecules from reaching the cell surface. In several cases, viruses actually hijack the Ub-proteasome system to degrade newly synthesized MHC Class-I molecules, thereby preventing surface presentation of viral peptides. Given its pervasive role in metabolic regulation, there is no doubt that many more human diseases will be shown to result from malfunction of the Ub-proteasome system.

Keywords

Catalytic Antibody
An antibody that catalyzes chemical reactions.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 11
Edited by Robert A. Meyers.
Copyright © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 3-527-30648-X

Catalytic Proficiency
A measure of the rate enhancement achieved in the presence of an enzyme; the dimensionless parameter ν_{enz}/ν_{non}, where ν_{enz} and ν_{non} are the reaction velocities in the presence and absence of an enzyme respectively.

Energase
A mechanochemical enzyme that catalyzes energy-dependent translocation, energy-dependent transport, and/or energy-dependent force production.

Enzyme
A biological catalyst that speeds up the making and breaking of chemical bonds without altering the reaction's equilibrium.

Protein Enzyme
A biological catalyst composed of one or more polypeptide chains.

RNA Enzyme
A biological catalyst composed of ribonucleic acid.

As is true of any catalyst, the defining quality of every enzyme is the ability to enhance chemical reactivity without altering the thermodynamic equilibrium of the reaction catalyzed. An enzyme's catalytic proficiency is measured by its rate enhancement factor, a parameter that equals ν_{enz}/ν_{non}, where ν_{enz} and ν_{non} are the reaction velocities in the presence and absence of an enzyme respectively. Although the rates of uncatalyzed reactions are often too slow to be determined under physiologic conditions, enhancement factors of enzymes are thought to range typically from 10^9 to 10^{17}, with a few approaching 10^{22} and others falling well below 100. Each catalytic cycle shares common features: (1) the enzyme must combine with its substrate, which is then converted into the transition state; (2) and this least stable reactant configuration then undergoes equipartition (i.e. half of the time, reforming EnzymeSubstrate complex, and just as often proceeding to form EnzymeProduct complex, the latter followed by product release). After each catalytic reaction cycle, an enzyme returns to its original form, such that an enzyme's action is without any effect on the reaction's equilibrium constant. Because product release is so often the slowest step in catalysis, discrete bond-making and bond-breaking steps, and even the formation of covalent intermediates, rarely hinder catalysis. The rates of highly perfected enzymes are limited only by the diffusion-limited availability of substrate; other enzymes are so sluggish that each complete catalytic cycle operates on the seconds to minutes timescale. In terms of natural selection, however, an organism accrues no competitive advantage should one of its enzymes evolve catalytic proficiency beyond that needed for efficient metabolism.

1
Enzymes as Life's Actuators

Because normal physiologic conditions (e.g. neutral pH, aqueous environment, moderate ionic strength, pressures near one atmosphere, and a narrow 0–50 °C temperature range) conspire to deactivate most chemical reactions, their uncatalyzed rates are frequently extraordinarily low. Consider, for example, the hexokinase reaction: $Mg{\cdot}ATP^{2-}$ + D-Glucose = D-Glucose 6-Phosphate + $Mg{\cdot}ADP^{1-}$. At cellular glucose and ATP concentrations, detectable glucose-6-P would require hundreds or thousands of years in the absence of hexokinase, but occurs in seconds at cellular enzyme concentrations. Even when nonenzymatic reactions are fairly fast, as is true for the reversible hydration of carbon dioxide to form bicarbonate anion, the presence of an enzyme (carbonic anhydrase, in this case) assures the reaction rate is always sufficient for effective metabolism.

The speed and specificity of enzyme-catalyzed reactions provides cells with the capacity to organize a series of these reactions into pathways responsible for the synthesis (*anabolism*) and breakdown (*catabolism*) of essential life-sustaining intermediates. With hexokinase as an example once again, exclusive phosphorylation at position-6 of the β-D-glucopyranose form would be impossible in the absence of enzyme. Even when nonenzymatic reactions are reasonably rapid, as in the case of reversible hydration of carbon dioxide to form bicarbonate anion, an enzyme is required to assure the reaction rate is sufficiently fast for efficient metabolism. In this respect, enzymes play roles analogous to on–off switches and amplifiers within electronic circuits. Substrate specificity also reduces the formation of toxic substances that would otherwise accumulate in side reactions. By coupling energy-requiring and energy-yielding reactions, enzymes also assist in managing cellular bioenergetics, thus permitting cells to store energy in many forms (e.g. as low molecular–weight metabolites, as macromolecules, as ion and solute concentration gradients, etc.). Enzymes catalyzing the first committed step in a metabolic pathway often possess regulatory sites that bind activators and inhibitors, allowing them to respond to regulatory cues as substances are produced or consumed within their own and other metabolic pathways. Moreover, because some enzymes are oligomeric (i.e. they are composed of multiple subunits), regulatory information can be transferred across their subunit–subunit interfaces in a manner that alters their catalytic efficiency in response to small fluctuations in the concentration of regulatory (or effector) molecules. This phenomenon, known as *cooperativity*, is attended by enzyme shape changes (i.e. allosteric transitions) that can greatly alter catalytic activity.

Certain highly specialized mechanochemical enzymes interact with their binding partners to adopt low- and high-affinity interaction states, the interconversion of which is driven by the Gibb free energy liberated upon the hydrolysis of certain metabolites, most often ATP or GTP. These affinity-modulated systems can also derive free energy during the dissipation of transmembrane solute concentration gradients. Such energy-transducing enzymes can also generate the forces needed for cell division and motility, solute transport, as well as intracellular trafficking, and sorting of molecules and/or organelles. By generating the

forces and mechanical work needed to power sensory processes, transport and translocation, and the ability to divide, these mechanochemical enzymes bestow upon organisms the essentially animating qualities of irritability, motility, and proliferation.

2 Chemical Nature of Enzymes

From earliest times, enzymes were invariably found to be associated with proteins. On the basis of his Nobel prize–winning work establishing the structures of heme and chlorophyll molecules, the German chemist Willstätter incorrectly asserted what he believed to be a universal principle, namely, that the catalytic entity of every enzyme would prove to be some small molecule that is bound to a protein that serves only passively as a stabilizing colloidal support. Sumner's crystallization of urease proved that the active enzyme is itself a protein, and this accomplishment earned him a Nobel Prize. However, while most known enzymes are proteins, others are partly or entirely composed of nucleic acid. Nobel laureates Cech and Altman demonstrated that certain RNA molecules are efficient catalysts of RNA self-splicing, phosphotransfer, and even peptide bond-forming reactions. These catalytic RNA molecules, also known as *ribozymes*, often achieve rate enhancements approaching 10^{11}. The hammerhead-shaped ribozyme was the first RNA motif observed to catalyze sequence- specific self-cleavage. With only around 30 nucleotides in their catalytic cores, these enzymes are among the smallest known catalytic RNAs. They display Michaelis–Menten kinetics, with Michaelis constants values ranging from 20–200 nM and turnover numbers in the range of $0.03\ s^{-1}$. Product release is generally fast, suggesting that the rate-determining step is phosphodiester bond-scission. Ribozyme-catalyzed phosphoryl transfer appears to involve destabilization of the substrate's ground state. This transesterification reaction is analogous to the catalytic mechanisms used by the mRNA spliceosome as well as DNA topoisomerases. Some evolution experts have argued that the likely early appearance of nucleic acids necessitated reliance on their catalytic properties in what might have been a ''preprotein'' biotic world.

One cannot dismiss the possibility that other biological substances (e.g. polysaccharides, complex lipids, etc.) may prove to be biological catalysts. The phenomenon of micellar catalysis, for example, is already firmly rooted in modern organic chemistry. In fact, some micellar catalysts even exhibit chiral recognition (i.e. the capacity to combine with and transform substrate molecules in a stereoselective manner). Whether the same holds for cellular membranes remains to be determined.

3 A Brief History of Enzyme Science

On the basis of his studies of diastase, a crude preparation of the enzyme α-amylase, the Swedish chemist Berzelius advanced the germinal concept that, to hasten product formation, a catalyst must first combine with its reactant. In keeping with his idea that a catalyst must weaken the bonds within a reactant, he coined the term *catalysis* by combining the Greek words *kata* (''break'') and *lyein* (''release'') to describe its ability to break apart chemical reactants. The birth of

the field of enzymology can be traced to 1810, when the French chemist and physicist Gay-Lussac demonstrated that anaerobic growth of yeast on sugars produces mainly ethanol and carbon dioxide. In 1878, Kühne coined the name enzyme, taken from the Greek words *en* (''within'') and *zyme* (''yeast''), to designate the fermentative catalyst within yeast. In 1896, Büchner successfully opened yeast cells in a mortar and pestle through the abrasive action of fine grains of sand on the microorganism's cell wall. Upon addition of sugars to this cell-free extract, he noted the evolution of CO_2 bubbles, a property that he took as a telltale sign of active metabolism. Büchner's sensational conclusion that biochemical reactions can occur outside a living cell gave birth to investigative enzyme chemistry and earned him the Nobel Prize. The discipline of enzyme kinetics was firmly established in 1913, when Michaelis and Menten published the famous rate law that now bears their names. A decade later, Briggs and Haldane introduced the concept of a steady state to enzyme kinetics and metabolism. By improving rapid mixing kinetic methods, Chance detected EnzymeSubstrate complexes spectrally and characterized their subsequent conversion to product. About the same time, Racker also discovered an enzyme (glyceraldehydes 3-phosphate dehydrogenase) that formed covalent enzyme–substrate intermediates during catalysis, thus dispelling notions that formation of covalently bound intermediates would be an unproductive detour (or *umweg*, as the German Nobelist Warburg put it), serving only to retard catalysis. Surging interest in shock waves and sonar during World War II, along with Einstein's extension of Maxwell's theory of chemical relaxation to include pressure-induced perturbations, provided an impetus for investigating the individual steps (or elementary reactions) within multistep mechanisms. For their pioneering work in developing and exploiting novel techniques that detect and quantify changes in rapid chemical and biological processes, Eigen, Norrish, and Porter shared the Nobel Prize in chemistry.

Enzymology is now a highly sophisticated and innovative discipline that continues to provide powerful insights into enzyme catalysis and metabolic regulation. Among its most notable contributors are: Abeles – for mechanism-based (or suicide) inhibitor design; Albery and Knowles – for enzyme energetics and catalytic perfection; Altman and Cech – for the discovery of catalytic RNA; Benkovic and Lerner – for catalytic antibodies; Boyer – for isotope tracer kinetics, equilibrium exchange theory, and ATP synthase binding change mechanism; Chance – for stopped-flow rapid mixing techniques, heme–protein kinetics; Cleland – for nomenclature, exchange-inert metal-nucleotides, exchange kinetics, and kinetic isotope effects; Cohn – for oxygen-18 probes of phosphotransfer reactions and NMR distance measurements; Eigen, De Maeyer, and Hammes – for temperature-jump reaction techniques to enzyme systems; Fersht – for site-directed mutagenesis as mechanistic probes as well as kinetic proofreading mechanism of protein folding; Frieden – for enzyme hysteresis; Fromm – for reversible inhibitors as tools for discriminating multisubstrate systems; Hartley – for burst kinetic methods for detecting reaction intermediates; Jencks – for catalytic strategies in chemistry and enzymology, as well as the conceptual basis for catalytic antibodies; Koshland – for the induced-fit hypothesis and cooperative ligand-binding

mechanisms; Mitchell – for the chemiosmotic principle; Monod, Wyman and Changeux – for cooperativity and allosteric models; Rose – for dynamic stereochemical probes and isotope trapping methods; Westheimer – for enzyme stereochemistry, stereochemistry of phosphoryl transfer, and photoaffinity labeling; and Wolfenden – for transition-state inhibitor theory and the conceptual basis of catalytic proficiency.

4 Systematic Classification of Enzyme-catalyzed Reactions

The number of classified protein enzymes now approaches 7000; fewer than several hundred reactions are known to require RNA enzymes. Given the diversity of living organisms, there must be thousands more that catalyze reactions remaining to be defined. The Enzyme Commission and the Joint Commission on Biochemical Nomenclature have distinguished enzymes into six chemically distinct classes, based entirely on the ways that enzymes break, rearrange, and form covalent bonds (See Table 1).

For more than a half century, enzymes have been named and classified only on the basis of the making and breaking of covalent bonds. There are, however, numerous examples of biological catalysis involving the interconversion of noncovalent substrate-like and product-like states. Consider the hundreds of mechanochemical enzyme reactions (see following text) that catalyze reactions that accomplish mechanical work or that generate force. Another prominent example is the entire group of so-called nucleotide exchange factors. These proteins play important physiologic roles, as illustrated by the facilitated exchange of solution-phase GTP with tightly bound GDP on GTP-regulatory proteins (or G-Proteins), resulting in the formation of G-ProteinGTP complex and solution-phase GDP. Another example is the adenine nucleotide exchange factor known as profilin (Reaction: $\text{Actin}\cdot\text{ADP} + \mathbf{ATP}_{\text{solution-phase}} = \text{Actin}\cdot\mathbf{ATP} + \text{ATP}_{\text{solution-phase}}$, where boldface type is used to indicate that exchange is the purely physical release of bound ADP, followed by binding of **ATP**). This uncatalyzed exchange reaction is too slow to sustain the high filament elongation rates (400–500 monomer per filament per second) during actin-based motility. To overcome this kinetic barrier, the protein profilin accelerates the ADP $\leftrightarrow$ ATP exchange reaction by a factor of 150, without any effect on the equilibrium constant for the exchange reaction. These features indicate that G-protein exchange factors and profilin must be regarded as biological catalysts, and hence as enzymes.

In the face of the growing number of instances where biological catalysis is not attended only by changes in covalent bonding, Purich offered a definition in 2001: ''An enzyme as a biological catalyst that facilitates the making and/or breaking of chemical bonds.'' While appearing to be no more encompassing than existing definitions of enzyme catalysis, the crucial difference lies in the use of *chemical* in place of *covalent* to describe the bonding changes. In *The Nature of the Chemical Bond*, Linus Pauling offered the following definition of chemical bonds: ''We shall say that there is a chemical bond between two atoms or groups of atoms in case that the forces acting between them are such as to lead to the formation of an aggregate with sufficient stability to make it convenient

Tab. 1 Systematic classification of enzyme-catalyzed reactions

Class 1: Oxidoreductases catalyze redox reactions.	
Dehydrogenase:	$Ethanol + NAD^{+} = Acetaldehyde + NADH + H^{+}$
Class 2: Transferases catalyze the transfer of functional groups.	
Sugar kinase:	$Glucose + MgATP^{2-} = Glucose = 6\text{-}P^{1-} + MgADP^{1-}$
Aminotransferase:	Oxaloacetate + Glutamate = Aspartate + 2-Oxoglutarate
Class 3: Hydrolases catalyze hydrolysis reactions.	
Esterase:	Ester + H_2O = Acid + Alcohol
Amidase:	Glutamiine + H_2O = Glutamic Acid + Ammonia
Phosphatase:	$Glucose\text{-}6\text{-}P^{2-} + H_2O = Glucose + HPO_4{}^{2-}$
Class 4: Lyases catalyze addition/elimination reactions.	
Fumarase:	Malate = Fumarate + H_2O.
Aspartase:	Aspartate = Oxaloacetate + NH_3
Class 5: Isomerases catalyze intramolecular rearrangements.	
Isomerase:	$Glucose\text{-}6\text{-}P^{2-} = Fructose\text{-}6\text{-}P^{2-}$
Class 6: Ligases catalyze joining reactions.	
Synthetase:	$Glutamate + NH_3 + MgATP^{2-} = Glutamine + MgADP^{1-}$
Polymerase:	$DNA_n + dNTP = DNA_{n+1} + PP_i$

for the chemist to consider it as an independent molecular species.'' Note that Pauling made no comment about covalent bonding. In this respect, because many protein conformational states and numerous ProteinLigand complexes are sufficiently long lived to exhibit chemically definable properties, their formation and/or transformation must be considered as chemical reactions. The same logic applies to the persistent, chemically definable position of a solute relative to the faces of a membrane, representing substrate-like and product-like states. For this reason, transporters should be regarded as enzymes. Finally, Purich in 2001 suggested that each mechanochemical ATPase can be termed an *energase*, a name he offered for those specialized enzymes catalyzing energy-dependent translocation, energy-dependent transport, energy-dependent force production, and so on. He also suggested that these mechanochemical enzymes should be considered as an entirely separate class, as these enzymes cannot be rationally accommodated in the current Enzyme Commission classification.

5 Mechanochemical Enzyme Reactions

There are literally hundreds of catalyzed force-generating and/or work-producing reactions that culminate in a change of some molecular condition (i.e. transport against a concentration gradient, locomotion against an opposing load, or stabilization of an otherwise unstable conformation/configuration). These reactions are typically driven by the Gibbs free energy liberated upon the hydrolysis of such molecules as ATP, GTP, P-enolpyruvate, and acetyl-phosphate. With the input of sufficient Gibbs free energy, these mechanochemical enzymes facilitate their reactions by interconverting between two or more noncovalent substrate- and product-like interactions states:

$$\text{Condition}_{\mathbf{A}} + \cdot ENZ \cdot \text{A}\mathbf{T}\text{P} = \text{Condition}_{\mathbf{A}} \cdot ENZ \cdot \mathbf{ATP} \quad (1)$$

$$\text{Condition}_{\mathbf{A}} \cdot ENZ \cdot \text{ATP} = \text{Condition}_{\mathbf{A}} \cdot ENZ \cdot \text{A}\mathbf{D}\text{P} \cdot \text{Pi} \quad (2)$$

$$\text{Condition}_{\mathbf{A}} \cdot ENZ \cdot \text{A}\mathbf{D}\text{P} \cdot \text{Pi} = \text{Condition}_{\mathbf{B}} \cdot ENZ \cdot \text{A}\mathbf{D}\text{P} + \text{Pi} \quad (3)$$

$$\text{Condition}_{\mathbf{B}} \cdot ENZ \cdot \text{ADP} + \text{A}\mathbf{T}\text{P} = \text{Condition}_{\mathbf{B}} + \cdot ENZ \cdot \text{A}\mathbf{T}\text{P} \quad (4)$$

$$\text{Condition}_{\mathbf{A}} + \text{ATP} = \text{Condition}_{\mathbf{B}} + \text{ADP} + \text{Pi} \quad \sum(1\text{–}4)$$

Note that the above reaction forms a catalytic reaction cycle, culminating in recycling of the enzyme to its initial form. In some cases (e.g. microtubule assembly/disassembly), the entire process may also require a considerable period of time to complete its cycle.

These reactions utilize Gibbs free energy liberated upon the hydrolysis of molecules such as ATP, GTP, P-enolpyruvate, and acetyl-phosphate. While certain bonds within these substances are thermodynamically highly unstable, they are highly stable kinetically. Mechanochemical enzymes share the capacity to catalyze the hydrolysis of these P–O–P or C–O–P anhydride bonds, thereby triggering a conformational transition from one interaction state to another.

Active solute transporters promote the transport of ionic and neutral solutes by forming a high-affinity TransporterSolute complex on the side of the membrane where the solute concentration is low. Hydrolysis of transporter-bound ATP subsequently drives the conversion of the high-affinity TransporterSolute complex into its low-affinity TransporterSolute complex, such that solute release is facilitated on the membrane's high-solute concentration side (see Table 2). In a similar manner, molecular motors power contractile processes, intracellular organelle trafficking, and cell crawling. Likewise, the building up and tearing down of supramolecular structures depends on ATP/GTP-driven affinity-modulated interactions (e.g. regulatory G-proteins, chaperonins, and proteasomes, and various other latching and switching molecules). The field of cell biology can be regarded as structural metabolism, where the supramolecular components are continually formed, remodeled, and degraded. Endocytosis and organelle traffic, cell crawling, signal transduction, and mitosis/meiosis are processes that are taking on the appearance of the pathways of intermediary metabolism. Even long-term potentiation, a neuronal process lying at the root of our memory and consciousness, is now known to depend on actin polymerization motors that remodel and maintain structures known as dendritic spines into functional neuronal synapses.

The essence of these energase-type enzymes is a molecular discrimination (or affinity-modulating) mechanism comprised of a succession of conformational states that transit between high- and low-affinity ligand interaction states. In a similar fashion, electron transport systems convert the free energy of NADH oxidation into the proton-motive force (pmf) driving ATP synthesis in oxidative phosphorylation. In its well-choreographed succession of electron transfer steps, a

Tab. 2 Mechanochemical enzymes: Affinity-modulated clamps, latches and switches

Reaction	*Energy source*	*High-affinity interaction partner*
Transporters	ATP	Ligand on low-concentration side of membrane
ATP synthase	ATP	Itself ($\alpha\beta-\gamma$ subunit interface)
Myosin	ATP	Actin filament
Electron transport chain	emf	Proton on high pH side of gradient
Dynein and kinesin	GTP	Microtubule
GTP-regulatory proteins	GTP	Target protein
DNA topoisomerase (type II)	ATP	Itself (at its dimer interface)
ATP sulfurylase	GTP	Active site
Actoclamplin	ATP	Clampin (Ena/VASP, N-WASP and formin protein families)

membrane-bound electron transport protein complex undergoes conformational change(s) altering the acidity of one or more acid-base groups, thus permitting the transmembrane protein to extrude one or more protons across a membrane bilayer. After NADH is formed upon the oxidation of foodstuffs, it undergoes oxidation (a net loss of electrons) and initiates the chemical reduction (a net gain of electrons) of electron transport proteins (ETP) situated in the inner mitochondrial membrane. Subsequent chemical reduction of molecular oxygen is mediated by various ETP complexes, resulting in the accumulation of protons within a submitochondrial compartment. Precisely how the electromotive force (emf) of electrochemical gradient generates the proton-motive force, remains an area of intense investigation. The current view is that electron transport drives a conformational change that lowers the affinity of carboxyl groups within the ETP complex for their protons. When viewed in this manner, the action of these multiprotein ETP complexes represents a highly specialized example of molecular discrimination.

6 The Catalytic Reaction Cycle

The long-standing problem in biological catalysis concerns the origin of enzyme rate enhancement and the functional coupling of enzyme and reactant in transformations of EnzymeSubstrate, EnzymeIntermediate, and EnzymeProduct complexes. The following table (Table 3) lists some of the ways in which an enzyme is thought to increase chemical reactivity. There is presently no single enzyme-catalyzed reaction for which the precise contribution of each factor has been unambiguously determined. The alert reader will also recognize that many of these factors are surely acting simultaneously and synergistically, and in various degrees, at defined stages in the reaction cycle.

Of all the explanations advanced to account for the catalytic proficiency of enzymes, the most appealing is that enzymes promote catalysis by stabilizing reaction transition states. This concept was assumed implicitly in writings of Haldane in 1930 and was explicitly stated by Pauling in 1940: ''In order to catalyze a reaction an enzyme must recognize the transition state in a selective way (i.e. it must

Tab. 3 Physicochemical factors thought to increase catalytic proficiency

Approximation	Enzymes increase the local effective reactant concentration by bringing reactants (as well as essential coenzymes and metal ion cofactors) into the vicinity of catalytic groups within the enzyme's active site.
Orientation	Enzymes adjust the mutual orientation of reactive groups on the substrate(s) and enzyme.
Push–pull catalysis	Enzymes have suitably positioned acid and base groups that can provide ("push") or withdraw ("pull") protons to and from the substrate, product or reaction intermediate at appropriate times in the reaction cycle.
Stereoselection	Enzymes possess the capacity to serve as three-dimensional templates that discriminate between various reactants on the basis of the stereochemical arrangement of their atoms.
Chelation	Enzymes and substrates often employ transition metal ions to form "bridge" complexes (e.g. enzyme–metal–ion substrate; enzyme–substrate–metal ion; or cyclic complexes as well).
Lewis acid effects	Enzymes use metal ions as electron-pair acceptors to polarize otherwise unreactive groups on the substrate or enzyme and/or to alter their acid/base properties.
Redox effects	Enzymes alter the redox properties of certain metal ions to transiently achieve oxidation states that would be otherwise unavailable in aqueous solutions.
Desolvation	Enzymes remove water molecules from the active site in order to increase the nucleophilic reactivity of functional groups on the substrate or enzyme.
Hydrophobic effects	Enzymes can alter the polar and apolar microenvironment within the active site to increase/decrease reactivity.
Proton shuttling	Enzymes create extended chains of hydrogen bonded water molecules that serve as "proton wires" for providing or removing protons from the active site on an as-needed basis.
Transition-state stabilization	Enzymes have active sites that are structurally complementary to one or more activated complexes formed along the reaction trajectory.
Ground-state stabilization	Enzymes can promote catalysis by destabilizing an otherwise unreactive ground-state enzyme–substrate complex.
Entropic effects	Enzymes can temporarily alter the thermodynamic properties of bound reactants in a manner that favors attainment of a highly reactive configuration.
Covalent catalysis	Enzymes can transiently form covalent intermediates that facilitate catalysis by managing the group transfer potential of reactants or by masking/unmasking functional groups to promote catalysis.
Entatic effects	Enzymes can speed up reactions by exerting substantial push–plull forces on reacting species, especially over short distances.

stabilize it better than the substrate).'' The following diagram (Fig. 1) illustrates this fundamental concept by comparing an uncatalyzed reaction proceeding through a highly unstable transition-state ($X^{\ddagger}$) and a hypothetical enzyme operating by a three-stage mechanism entailing the formation of an Enzyme·Substrate complex (E·S), an Enzyme·Transition State ($E{\cdot}X^{\ddagger}$), and an Enzyme·Product complex (E·P). Note that the stabilization free energy may be written as: $\Delta\Delta G^{\ddagger} = \Delta G^{\ddagger}_{\text{non}} - \Delta G^{\ddagger}_{\text{enz}}$, where $\Delta G^{\ddagger}_{\text{non}}$ is the energy change for forming the nonenzymatic transition state, and $\Delta G^{\ddagger}_{\text{enz}}$ is the energy change for forming the enzymatic transition state. On the basis of absolute rate theory, the $v_{\text{non}}/v_{\text{enz}}$ may be estimated from the relationship: $v_{\text{non}} = v_{\text{enz}} e^{-\Delta\Delta G^{\ddagger}/RT}$, where R and T are the universal gas constant and the absolute temperature.

Hammes in 2002 offered the view that ''when a substrate binds to an enzyme, it becomes an integral part of the macromolecule. The subsequent dynamics of the macromolecular conformational changes are then the catalytic process itself. This view of catalysis means that the making and breaking of noncovalent bonds within the structure are part of the catalytic process, and that these events can occur close to and far from the active site. The advantage of having hundreds of intramolecular interactions dynamically involved in catalysis is that the energetics of the reaction can be easily manipulated to produce catalysis, and extremely fine tuning is provided by hundreds of intramolecular interactions. This mechanism could be viewed as a ''gear shift'' mechanism: the conformational transitions are analogous to shifting gears, and the interactions between the enzyme and substrate correspond to the gear coupling mechanism. Asking what ''drives'' the reaction is not terribly meaningful, as the essence of cooperative processes is that many events are occurring essentially simultaneously.''

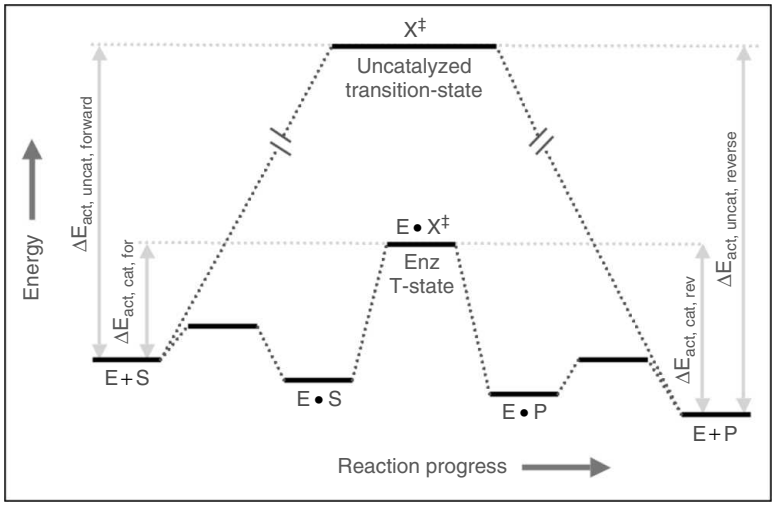

Fig. 1 Reaction coordinate diagram illustrating the steps in an uncatalyzed reaction (upper pathway) and those in an enzyme-catalyzed process (lower pathway). Note that the energy of the initial and final states are the same for the enzymatic and nonenzymatic processes.

These fundamentally important ideas are tantamount to saying that an enzyme creates a catalytic environment, one that dynamically promotes the reaction trajectory from substrate to product. Although $E{\cdot}X^{\ddagger}$ has been widely employed to represent the transition state, the latter should be represented as $(E{\cdot}X)^{\ddagger}$ to indicate that enzyme and substrate are mutually altered as the catalytic reaction cycle proceeds. That enzyme and substrate jointly reach the transition state also complies with the principle of thermodynamic reciprocity, which requires that substance a cannot affect substance without the latter likewise affecting the former. Traditional use of $E{\cdot}X^{\ddagger}$ leaves a mistaken impression that the enzyme is an immutable template, such that only the substrate reaches the activated transition-state configuration.

The chief ambition of enzyme chemists is to understand the catalytic process used by enzymes by obtaining a complete description of all of the physical and chemical events occurring during an enzyme-catalyzed reaction. Such a daunting undertaking inevitably leads to the formulation of a reaction mechanism, a chemical model or framework consisting of all of the elementary reactions comprising the overall catalytic process. The mechanism must be consistent with the reaction's overall stoichiometry and stereochemistry, its kinetic and thermodynamic properties, the structures of detected intermediates and inferred transition state(s), the energetics of intermediates involved in rate-determining step(s), as well as effects of temperature, ph, ionic strength, and solvent. modern enzymology has benefited enormously from the atomic level molecular structures, as provided by X-ray crystallography and high-resolution, multidimensional nmr spectroscopy. even so, while structural biologists have glimpsed various stages of catalysis, there is no such thing as a ''tell-all motion picture'' of even the simplest catalytic process. Enzyme chemists must also rely on stereochemistry to learn whether certain covalent intermediates are formed during catalysis. The optimal approach is to construct hypotheses offering testable predictions that can be recursively tested in kinetic experiments designed to discriminate among rival explanations or at least to suggest a more definitive experiment.

Intensive investigation of proteolytic enzymes over the past half century has culminated in a self-consistent mechanism for chymotrypsin catalysis (Fig. 2). This enzyme cleaves peptide bonds where the carboxyl group–donating residue contains a hydrophobic side chain. The reaction is facilitated by push–pull acid/base interactions involving three residues common to hundreds of other mechanistically related ''serine'' proteases. An acyl-serine intermediate permits one product (designated by the R-group) to dissociate such that water can replace the departing amino group in a manner that leads to hydrolysis of the peptidyl-acyl-enzyme and subsequent release of the second peptide fragment (designated by R′).

Enzyme chemists are reasonably confident of the general outline of this reaction mechanism, especially in the light of the wealth of structural, chemical, and kinetic information gleaned from persistent and systematic investigation. That said, there remain obvious voids in our understanding of chymotrypsin catalysis. A major limitation stems from an almost exclusive reliance on data obtained from the use of synthetic chromogenic substrates (i.e. molecules that generate spectral change

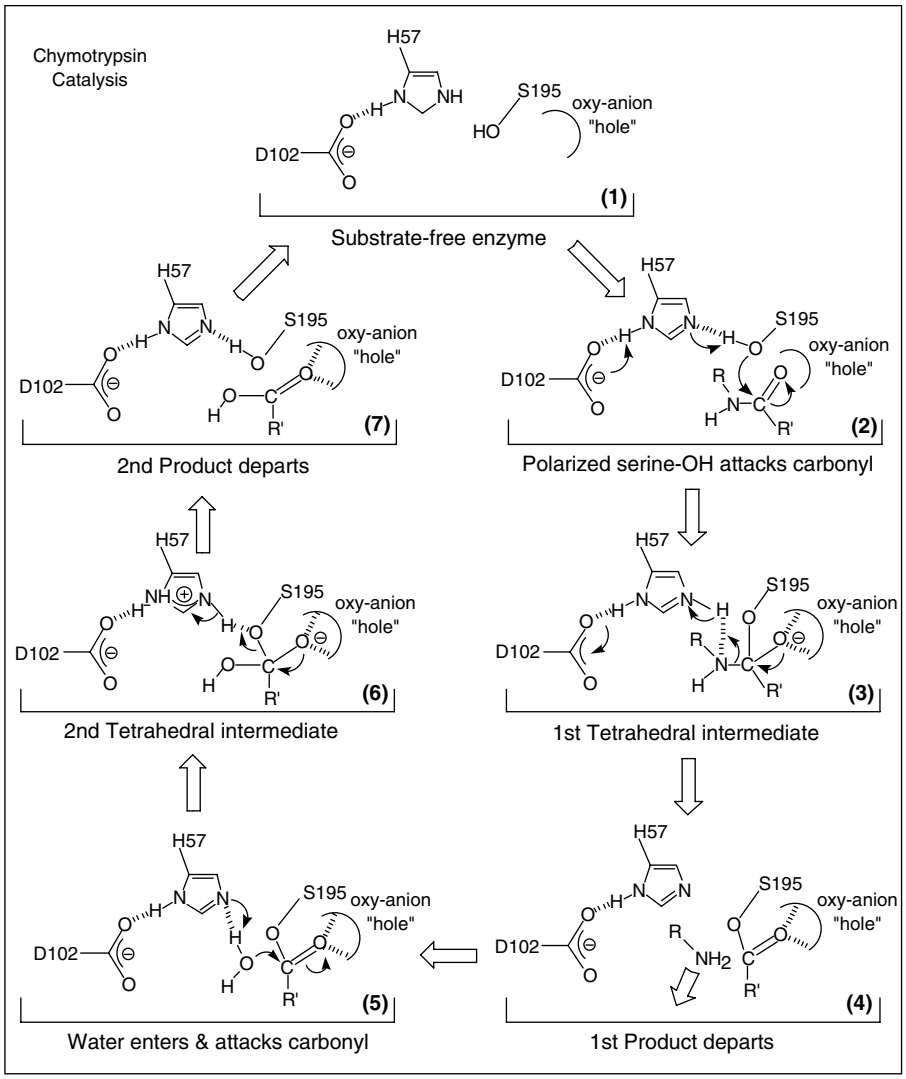

Fig. 2 Catalytic mechanism of the proteolytic enzyme chymotrypsin. The substrate-free enzyme (**1**) with its triad of aspartate, histidine, and serine residues, as well as a diagrammatic representation of the positively charged residues making up the ''oxy-anion hole''. The triad is thought to facilitate nucleophilic attack of the serine hydroxyl group, as shown in (**2**), thereby forming a negatively charged tetrahedral intermediate (**3**) that rearrange to the *O*-acyl-enzyme (**4**). The reaction cycle proceeds after the amine-containing product departs and is replaced by a water molecule (**5**). Nucleophilic attack by water then forms the second tetrahedral intermediate (**6**), which rearranges to form the second product-bound (**7**). The same mechanism applies to ''serine'' protease/esterase superfamily.

in the visible and/or ultraviolet spectrum upon peptide bond cleavage). Virtually nothing is known about chymotrypsin's action on natural protein substrates.

Whenever it becomes feasible to explain the nature of biological catalysis, biochemists can also begin to understand the structural, dynamic, and catalytic features responsible for effective regulation. Activators and inhibitors of enzymes have the effect of respectively lowering and raising reaction barrier(s), as do the activating and inhibitory effects of posttranslational covalent modifications of enzymes. Another benefit of developing detailed, well-reasoned models for enzyme catalysis is the improved prospect for designing highly effective inhibitors that may be employed as therapeutic agents. Not surprisingly, pharmaceutical companies continually make huge investments of time and money in their investigative efforts to gain such valuable information about key enzyme reactions. An excellent example is angiotensinogen-converting enzyme (ACE), for which well over a million compounds have been synthesized and evaluated in terms of their potential to become reliable blood pressure–regulating drugs.

Finally, a long-standing aspiration in chemistry is the creation of synthetic molecules that attain the stereochemical selectiveness, if not the catalytic proficiency, of naturally occurring enzymes. The rationale for this approach is to circumvent the limited stability of proteins, especially in nonaqueous solutions. One approach for obtaining novel catalysts for specific organochemical reactions involves the creation of catalytic antibodies (or ''abzymes''). The idea that enzymes promote catalysis by stabilizing reaction transition states led Jencks in 1969 to offer the following prediction that appropriately selected antibodies would prove to be effective catalysts. ''If complementarity between the active site and the transition state contributes significantly to enzymatic catalysis, it should be possible to synthesize an enzyme by constructing such an active site. One way to do this is to prepare an antibody to a antigenic group which resembles the transition state of a given reaction. The combining sites of such antibodies should be complementary to the transition state and should cause an acceleration by forcing bound substrates to resemble the transition state.'' Because transition states are intrinsically unstable, catalytic antibodies are selected by using chemically stable transition-state analogs as immunigens. For example, antibodies generated against a bent porphyrin ring were found to catalyze the metal ion insertion into heme groups, presumably by straining the planar substrate toward a bent transition-state conformation. Extensive investigations, chiefly in the laboratories of Lerner and Benkovic, demonstrated that the observed rate enhancements correlated with an antibody's affinity for analog versus that for the reactant. While many details of antibody catalysis remain to be elucidated, it is safe to assert that antibodies are unlikely to approach the efficiency of enzymes, at least not in the foreseeable future. Beyond stabilizing one or more transition states in a catalytic reaction cycle, synthetic enzymes must also undergo an intricate series of energetically and temporally controlled conformational changes, which permit naturally occurring enzymes the capacity to control their acid/base, nucleophilic, electrophilic, and/or redox chemistry. Achieving the skill and insight to ''teach'' synthetic catalysts the finely honed art of catalysis remains a stubbornly elusive goal in modern enzyme science.

7
Basic Enzyme Kinetics

The Michaelis–Menten treatment of enzyme-catalyzed reactions is based on the following key assumptions: (1) the enzyme combines rapidly and reversibly with the substrate to form a single E·X complex, such that the Michaelis constant K_S equals $\{([E_{total}] - [E{\cdot}X]) \times ([S_{total}] - [E{\cdot}X])\}/[E{\cdot}X]$; (2) the total enzyme concentration is negligible relative to the total substrate concentration (i.e. $[E_{total}] \ll [S_{total}]$), thereby simplifying the earlier expression to: $K_S = \{([E_{total}] - [E{\cdot}X]) \times [S_{total}]\}/[E{\cdot}X]$; (3) the reaction rate (i.e. $v = k_{cat}\ [E{\cdot}X]$) is constant during the initial reaction phase, when substrate consumption and product accumulation is minimal; and (4) the concentration of active enzyme remains unchanged. The resulting Michaelis–Menten rate equation is:

$$v = V_{max}[S]/\{K_S + [S]\}$$

where V_{max} is the maximal rate (units = Molarity per second). [Note: $V_{max}/[E_{total}]$ equals the catalytic constant k_{cat} (units = second^{-1}), a measure of the frequency of catalytic cycling.] In more rigorous steady state treatments, particularly those accounting for isomerizations among many enzyme-bound species (e.g. $E + S = E{\cdot}S_1 = E{\cdot}S_2 = \cdots E{\cdot}S_n \cdots = (E{\cdot}X)^{\ddagger} = E{\cdot}P_n \cdots = E{\cdot}P_2 = E{\cdot}P_1 = E{+}P$), the Michaelis constant K_M (units = Molarity) is more complicated than the thermodynamic parameter K_S. For this reason, the Michaelis constant should not be regarded as an accurate measure of the dissociation constant for the E·S complex.

Most enzyme-catalyzed reactions actually utilize more than one substrate, especially when ATP, NAD^+, Coenzyme A, and similar cosubstrates are required. The kinetic behavior of multisubstrate enzyme systems depends on the order in which substrates bind and products are released. In hydrolase-type reactions, water is the second substrate; however, its concentration (55.5 M) is so high that, for kinetic purposes, water cannot be treated as a variable.

8
Enzyme Regulation

Homeostasis arises from the ability of enzymes, membrane-bound and mobile receptors, as well as key regulatory proteins to sense changes in the concentration of substrates, coenzymes, activators, as well as inhibitors, to integrate these input signals and to make appropriate responses that modify metabolic activity. Of particular significance are the enzymes catalyzing the first committed reactions within a pathway, and often play a pacemaking role in controlling metabolic flux (or throughput). Other enzymes within a pathway may simply adjust their individual catalytic properties in response to changes in the availability of pathway intermediates. Because most pathways are interconnected at branch points (or nodes), enzymes catalyzing first steps of pathways must be regulated in a hierarchical manner. Fast signaling occurs on the millisecond-to-second timescale and requires rapid binding and release of regulatory molecules to and from specific binding sites on target enzymes. On the second-to-minute timescale, cellular regulation is achieved by hormone and/or effector controlled enzymes catalyzing posttranslational modifications (e.g. phosphorylation, methylation, nucleotidylation, ADPRibosylation, acetylation, proteolysis, etc.) of

target enzymes, thereby altering the latter's catalytic performance. Subsequent removal of the transferred group by certain phosphatases, phosphodiesterases, glycosylases, and hydrolases restores the target enzyme's original activity state. Regulatory processes taking place on the minutes-to-days timescale often reflect changes in the rates of biosynthesis or degradation of regulated enzymes. Some enzymes have short biological half-lives (e.g. 12 min for ornithine decarboxylase), whereas others, like lactate dehydrogenase, are highly stable and persist for weeks or longer.

Feedback inhibition allows enzymes catalyzing committed steps to be inhibited as pathway end products eventually accumulate. Feedback inhibitors most often bind at discrete regulatory sites that are topologically remote from the active site, and they possess the ability to modify catalytic activity by altering the properties of active-site residues. Inhibitors have a net effect of raising the height of energy barriers limiting the rate of substrate binding and/or catalysis; activators have the opposite effect. It should be stressed that feedback inhibition at pathway branch points presents the opportunity for highly coordinated metabolic regulation of highly branched metabolic networks.

The most common mode of enzyme regulation results from spontaneous or ligand-induced conformational changes. In the case of spontaneous changes, a protein may exist in two states X and Y that are in thermodynamic equilibrium with each other. The equilibrium concentrations of X and Y are determined by the relative stabilities of each conformation. In other cases, a ligand molecule selectively alters the stability of one conformational state of the enzyme. In either case, structural alterations may arise from short-range effects (i.e. at distances much less than a nanometer) or they can occur from long-range changes at the quaternary structural level (i.e. through rearrangements in subunit–subunit interactions). The term *allostery* is derived from the Greek prefix *allo* (meaning ''another'') and the suffix ''steros'' (meaning ''shape'' or ''form''). Allosteric interactions are attended by changes in substrate binding affinity and/or catalytic efficiency, by raising or lowering thermodynamic barriers for substrate binding and/or catalysis. Allosteric activators have the net effect of increasing an enzyme's affinity for its substrate(s) and/or its catalytic performance; allosteric inhibitors have the opposite effect.

Unlike those enzymes lacking regulatory mechanism, almost every allosteric enzyme possesses multiple, mutually interactive subunits, each with its own active site and one or more sites for activators and/or inhibitors. Cooperativity is the phenomenon wherein effector molecule binding on one subunit of an oligomeric protein results in local structural changes that are communicated to and from sites on other subunits. In the Monod–Wyman–Changeux concerted transition model, an oligomeric protein undergoes an all-or-none transition in response to changes in the concentration of effector molecules; alternatively, in the Adair–Koshland model, the conformational changes occur sequentially, again in response to changes in regulatory molecule concentration. Such binding interactions alter catalytic activity, often over narrow ranges of substrate and/or effector concentrations. The need for such responsiveness becomes clear where one realizes that most enzymes are not particularly responsive to changes in the

concentration of input signals. Enzymes obeying the Michaelis–Menten kinetics (see preceding text) require large changes in substrate concentration, whereas the activity of highly cooperative enzymes responds over a more narrow concentration range.

9 Inborn Errors in Enzyme Function

Genetic mechanisms minimize the occurrence of mutant enzymes that improperly catalyze a reaction or inappropriately respond to regulatory cues. Such renegade enzymes can wreak havoc on cells, tissues, and organs. Biomedical research has uncovered countless instances wherein improper catalysis/control of even a single enzyme can greatly distress a living organism. In fact, many animal and plant diseases arise from point mutations altering enzyme efficiency through an incorrect substitution of a single amino acid. Other injurious mutations result in over/underproduction of enzymes, defective regulatory interactions, impaired stability, incorrect posttranslational modification, improper subcellular targeting, and so on. Diseases are linked to the failure of specialized enzymes designed to remediate any DNA damage arising from photolysis, oxidation, hydrolysis, racemization, and other molecular rearrangements. A notable example of an enzyme-associated pathophysiology is amyotrophic lateral sclerosis (ALS) (also known as *Lou Gehrig's disease*), a terrible neurodegenerative disorder linked to impaired action of superoxide dismutase. This enzyme plays a powerful role in mitigating oxidative stress by catalyzing the conversion of two superoxide ($O_2^{\bullet -}$) ions to produce dioxygen and the less toxic substance, hydrogen peroxide. Excess superoxide destroys essential cellular components, especially in neurons where oxidative stress has profound pathological sequelae. Another example, taken from research on Alzheimer's disease, is the very finding that enzyme-catalyzed prolyl isomerization can regulate folding of the cytoskeletal protein Tau in axons, such that enzyme knockouts in mice bring about progressive age-dependent neuropathy characterized by motor and behavioral deficits, tau hyperphosphorylation, paired helical filament formation, and neurodegeneration. Finally, the devastating effects observed in primary oxalemia have been traced to the mistargeting of an oxalate-degrading enzyme from peroxisomes to mitochondria.

Keywords

Amber
The name given to the UAG stop codon, which is the least used of the three stop codons in *E. coli* and yeast.

Amber-suppressor tRNA
A tRNA that is capable of decoding the *amber* stop codon, UAG, is said to ''suppress'' *amber* nonsense mutations.

Aminoacyl-tRNA Synthetase (aaRS)
An enzyme capable of esterifying an amino acid onto a tRNA. These enzymes activate free amino acids to adenylates using ATP, and some actively ''edit'' misacylated tRNAs by hydrolysis of the errant amino acid.

Codon
The unit of mRNA that codes for an amino acid. Natural codons are three consecutive ribonucleotides (G, A, U and C); there are therefore 64 natural codons of which three (UAG, UGA, and UAA) code for termination of protein synthesis (i.e. ''stop''). Codons are read by complementarity to anticodons on tRNAs at the ribosome.

Identity Element
The portions of tRNAs responsible for conferring specificity for a cognate aminoacyl-tRNA synthetase.

Library
A collection of related molecules that vary in a specified way, typically synthesized in a highly parallel fashion. For example, a library might consist of a large collection of mutants of a specific protein, such as an aminoacyl-tRNA synthetase.

Orthogonal Pairs
Aminoacyl-tRNA synthetases and their tRNA substrates that do not interact with the tRNAs and synthetases of the host cell in which they are expressed.

Selection
A procedure for sorting cells on the basis of their ability to survive under specified conditions. Selections can be used to sort libraries of enzymes expressed in cells,

if the survival of the organism requires the activity of the enzyme. In contrast, a screen is a procedure for sorting cells on the basis of phenotype, such as fluorescence.

tRNA
Small RNAs, typically about 75 nt ending with the sequence CCA-3′, which deliver amino acids for protein synthesis at the ribosome in response to the mRNA codons to which they correspond. tRNAs are acylated with amino acid by aminoacyl-tRNA synthetases.

Unnatural Amino Acids
Protein monomer building blocks not inserted by the biosynthetic machinery of living organisms. There are 20 natural amino acids normally incorporated into proteins.

The Genetic Code consists of 64 three-base codons that code for 20 amino acids and three stop signals. Recent engineering of the cell's protein synthesis machinery has allowed unnatural amino acids to be encoded in the genetic code of prokaryotic and eukaryotic organisms. Importantly, the approaches discussed add unnatural amino acids to the genetic code, without detracting from the cell's ability to incorporate the common 20 amino acids into proteins. Here we discuss the intellectual and practical strategies that have been employed in the challenging, but ultimately successful expansion of the genetic code. We also discuss the emerging applications of expanded genetic codes in solving basic biological and biophysical problems and in creating a new synthetic biology.

1
Expanding the Genetic Code

1.1
The Chemical and Biosynthetic Incorporation of Unnatural Amino Acids into Proteins

One of the remarkable chemical mysteries of life is that molecules composed of just 20 amino acid monomers carry out the entire repertoire of protein function – which spans structural roles, metabolism, signal transduction, immunity, replication and degradation, to name just a few. The chemical repertoire of proteins is naturally enlarged by the occasional insertion of selenocysteine or pyrrolysine, and by the common addition of posttranslational modifications (including phosphorylation, sulfation, lipidation, biotinylation, glycosylation, hydroxylation, methylation and acetylation), particularly in higher organisms. Those taking a chemical approach to biology have long recognized that expanding and precisely controlling the functionalities that can be incorporated into proteins would allow the creation of powerful tools for enzymatic, biophysical, and cellular studies. Despite its obvious utility, achieving the facile incorporation of "unnatural" amino acids has been and continues to be a difficult problem.

A number of methods have been developed for the insertion of unnatural amino acids into proteins, from synthetic to biosynthetic. Solid-phase peptide synthesis combined with enzymic or chemoselective ligation now permits the *in vitro* synthesis of small proteins with total control over the amino acid composition. Larger proteins are accessible *in vitro* using semisynthetic methods such as expressed protein ligation, wherein a synthetic peptide is chemoselectively ligated to a recombinant protein fragment. Biosynthetic approaches give access to essentially any size protein, but have their own limitations. For example, addition of near-homologs of natural amino acids (such as selenomethionine) to the growth medium sometimes results in widespread replacement of a natural amino acid, but, while useful, this does not actually expand the genetic code. Site-specific biosynthetic expansion of the genetic code has been achieved by chemical esterification of a tRNA with an unnatural amino acid, both in cell-free translation systems and with microinjection or electroporation of cells. Here, the rarest stop codon is used as a "blank" in the genetic code, read by the esterified tRNA. While this is a powerful approach, its use has been limited by the heroic synthetic effort required. Recent ribozyme-based approaches for acylation of tRNAs with unnatural amino acids may expand the scope of this method.

A quantum leap forward has occurred in recent years in this field – the first organisms have been engineered that site specifically utilize a twenty-first amino acid monomer. One advantage to this approach is that the researcher need only transform an expression vector for the protein of interest into a strain with the appropriate biosynthetic machinery, and addition of unnatural amino acid to the growth medium results in protein containing unnatural amino acid. The ease of use finally makes available proteins with unique reactive handles, homogeneous posttranslational modifications, and intrinsic biophysical probes, to the experimentalists such as enzymologists and cell biologists who can make the best use of them. Here we describe the engineering of prokaryotic and, more recently, eukaryotic organisms with expanded genetic codes, highlighting uses, challenges and future directions.

1.2 A General Strategy for Expanding the Genetic Code of Organisms

Expanding the genetic code of an organism involves the addition of an unnatural amino acid to the organism's genetic repertoire without loss of the ability to insert any of the 20 natural amino acids into proteins. An organism with an expanded genetic code will incorporate unnatural amino acids at specific sites in a protein in response to a unique codon, through a unique enzyme (an aminoacyl-tRNA synthetase) capable of acylating a tRNA for delivery of the unnatural amino acid in response to that codon (see Fig. 1). Ideally, the amino acid will be incorporated with a fidelity rivaling that for natural amino acid–incorporation. To achieve an organism with an expanded genetic code, the following are required:

1. A host organism: Owing to the extensive engineering required to expand the genetic code, well-understood systems like *Escherichia coli* and yeast have proven good starting points.
2. An insertion signal (codon): The *amber* stop codon is a good first choice, since it is rarely used in *E. coli* and yeast, and

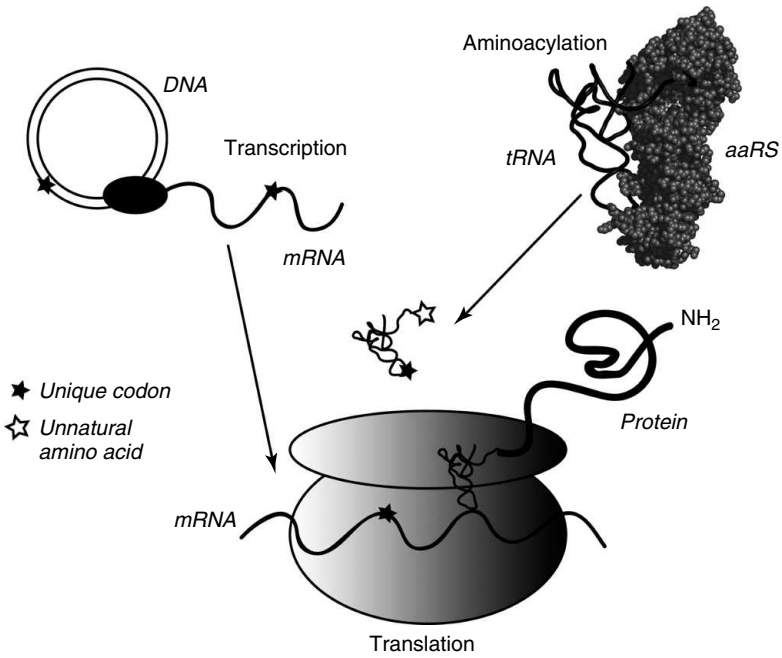

Fig. 1 Scheme of protein biosynthesis: Expansion of the genetic code first requires a unique codon (e.g. *amber* stop codon or 4-base codon), which is specified in the DNA and transcribed into the mRNA. A unique aminoacyl-tRNA synthetase (aaRS) must acylate a unique tRNA with the unnatural amino acid. This tRNA then delivers the unnatural amino acid to the ribosome in response to the unique codon, incorporating it into protein site specifically.

since robust ''suppressors'' of *amber* mutations are known. Expansion of the genetic code with multiple distinct unnatural amino acids is possible using extended insertion signals such as four-base codons.

3. An ''orthogonal'' tRNA corresponding to the insertion signal that is neither acylated nor deacylated (''edited'') by any endogenous aminoacyl-tRNA synthetase (aaRS).
4. An orthogonal aaRS, that acylates only the orthogonal tRNA, and only with an unnatural amino acid. For simplicity, an aaRS without hydrolytic editing is a good choice.
5. An unnatural amino acid that is neither toxic nor incorporated into proteins by endogenous aaRSs, but that is readily taken up by the cell (or produced there).

1.3 Unique Codons

The genetic code consists of 64 three-base codons that code for 20 amino acids and three stop signals. Since only one stop codon is needed for translational termination, the other two can in principle be used to encode unnatural amino acids. The *amber* stop codon (UAG) has been extensively used in the *in vitro* and *in vivo* biosynthesis of unnatural amino acid–containing proteins. This codon is also the least used stop codon in both *E. coli* and in yeast, and several laboratory *E. coli* strains

contain suppressors that insert a natural amino acid in response to UAG without significantly affecting growth rates. Suppressors have also been discovered for *amber* codons in mammalian cells and in higher organisms, such as yeast, worms and mice. It should therefore be possible to incorporate unnatural amino acids in response to an *amber* codon in a range of host organisms from prokaryotes to eukaryotes without significant perturbation of the host. In fact, orthogonal pairs that decode *amber* codons and insert unnatural amino acids have been developed for *E. coli*, yeast, and mammalian cells.

An alternative and potentially complementary set of codons to the *amber* codon are four-base and other extended codons. Naturally occurring frameshift suppressors in yeast and *Salmonella* are known, typically functioning by decoding a 4-base codon using a tRNA with an extended anticodon loop (8 nt instead of 7 nt). Suppression of 4-base and 5-base codons has been demonstrated in *E. coli* and in *E. coli* cell-free translation systems. Variants of $tRNA^{Ser}$ with randomized, extended anticodon loops (8 or 9 nt instead of 7 nt) have been selected for the ability to suppress randomized four-base codons in the gene for β-lactamase. The selected variants included suppressors for the codons AGGA, UAGA, CCCU, and CUAG, with efficiencies comparable to *amber* suppression. A similar approach afforded fairly efficient 5-base codon suppressors of CUAGU, CUACU, and AGGAU.

In practice, it has been demonstrated that a four-base codon AGGA and the *amber* codon UAG can be used to direct the incorporation of two distinct unnatural amino acids into a single site in protein in *E. coli* with high fidelity and specificity. Moreover, simultaneous insertion of two unnatural amino acids has been accomplished in cell-free transcription/translation systems with two 4-base codons. The number of 4-base codons with reasonable suppression efficiency probably places a small, finite upper limit (perhaps 4) on the number of amino acids that can be inserted this way. An alternative approach is to develop ''unnatural codons'' that utilize a nonnatural base pair, and this is actively being pursued by several groups. The ability to generate a stable base pair that can faithfully be enzymatically incorporated into both DNA and RNA in living cells (which must make or uptake the monomers) is a difficult problem that is still far from a practical solution.

2 Expanding the Genetic Code of Bacteria

2.1 Orthogonal Aminoacyl-tRNA-Synthetase/tRNA Pairs for Bacteria

The first stage in expanding the genetic code of an organism is to generate an orthogonal tRNA/aaRS pair, and second, to change the specificity of the aaRS with respect to amino acid. (Hereafter, the notation $Oo tRNA^{Aaa}$(NNN) for tRNAs and *Oo*AaaRS for aminoacyl-tRNA synthetases shall be used, where *Oo* denotes the organism, Aaa denotes the amino acid, and NNN denotes the anticodon.) All initial work was carried out in *E. coli* using *amber*-suppressing tRNAs. The Schultz laboratory first employed an engineering approach to generate an orthogonal tRNA/synthetase pair based on the exceedingly well-characterized *E. coli* glutaminyl-tRNA synthetase/$tRNA^{Gln}$(CUA) pair. (GlnRS naturally acylates an efficient *amber*

suppressor in *E. coli*.) Despite a remarkable change in specificity toward the orthogonal tRNA, the engineered mutant GlnRS was still capable of efficiently acylating the wild-type $tRNA^{Gln}$ as well. If the amino acid specificity of this enzyme had been subsequently altered, the unnatural amino acid would have been inserted at Gln codons throughout the proteome, in addition to *amber* codons.

Selection against aminoacylation of endogenous wild-type tRNAs might lead to aaRSs with specificity for the orthogonal tRNA. RajBhandary and coworkers pursued such a strategy with a mutant *E. coli* initiator tRNA that is not aminoacylated by endogenous synthetases and the tyrosyl-tRNA synthetase from *Saccharomyces cerevisiae*. The wild-type *Sc*TyrRS also aminoacylates *E. coli* $tRNA^{Pro}$, and is therefore toxic in *E. coli*. However, when a library of *Sc*TyrRS mutants was screened simultaneously for a lack of toxicity and the ability to suppress *amber* mutations in the gene for chloramphenicol acetyltransferase (which confers resistance to the antibiotic chloramphenicol), nontoxic variants of TyrRS were isolated, which discriminated 15-fold against *E. coli* $tRNA^{Pro}$.

A second strategy for generating new orthogonal pairs involves importing a heterologous *amber*-suppressor aaRS/tRNA pair from another organism. This approach was, in part, driven by the observation that the identity elements in tRNAs for eukaryotic aaRSs often differ significantly from their prokaryotic counterparts. Many eukaryotic aminoacyl-tRNA synthetases therefore do not charge *E. coli* tRNAs and should be orthogonal in *E. coli*. In particular, several yeast synthetases (notably glutamine, aspartic acid, arginine, and tyrosine) do not aminoacylate total *E. coli* tRNA, and might be useful for the construction of orthogonal tRNA-synthetase pairs.

On the basis of the observation that *S. cerevisiae* $tRNA^{Gln}$ (*Sc*$tRNA^{Gln}$) is not acylated by *E. coli* GlnRS (*Ec*GlnRS), Liu and Schultz demonstrated that a modified *Sc*$tRNA^{Gln}$(CUA) and *Sc*GlnRS constitute a functional orthogonal pair in *E. coli*. Despite nearly 10 man-years of work engineering this pair, it was not possible to alter the amino acid specificity of *Sc*GlnRS, even though much of the selection and library construction technology was worked out on this system.

Archaeal tRNA synthetases are more similar to their eukaryotic than prokaryotic counterparts in terms of homology and tRNA identity elements. However, unlike synthetases from eukaryotic cells, synthetases from archaea can be expressed in good yields in *E. coli* and can be readily purified in active form. Numerous archaeal genome sequences are currently available, which, together with the absence of introns in archeal genomes, facilitate the cloning of the archaeal synthetase genes. Moreover, early work on the halophile *Halobacterium cutirebrum* indicated that almost all its tRNAs (notably those for leucine, arginine, tyrosine, serine, histidine, and proline) cannot be charged by *E. coli* aminoacyl-tRNA synthetases, suggesting that these tRNAs are potentially orthogonal in *E. coli*. Consequently, attention has recently focused on the archaea, rather than on eukaryotes, as a source of orthogonal tRNA-synthetase pairs for *E. coli*.

It was shown that a $tRNA^{Tyr}$(CUA) and TyrRS from the archea *Methanococcus jannaschii* constitute an orthogonal pair in *E. coli*. However, while the *Mj*TyrRS is considerably more active than *Sc*GlnRS, the *Mj*$tRNA^{Tyr}$(CUA) was not ''as orthogonal'' as *Sc*$tRNA^{Gln}$(CUA); that is: the

*Mj*tRNA^{Tyr}(CUA) is detectably acylated by *E. coli* synthetases. A semirational design strategy was used to increase the orthogonality of this tRNA using a variant of the "double-sieve" selection for unnatural amino acids (see the following section). The resulting orthogonal tRNA/synthetase pair has been the most useful one so far in *E. coli*, due to the high activity of the synthetase and good orthogonality of the tRNA. The relatively large, hydrophobic amino acid binding pocket of TyrRS has allowed the incorporation of many useful amino acids. Recently, solution of the *Mj*TyrRS crystal structure permitted design of a mutant synthetase with better recognition of the *Mj*tRNA^{Tyr}(CUA), which may be useful in further work altering the amino acid specificity of the synthetase.

A number of other pairs have also been introduced into *E. coli* including yeast tRNA^{Asp}(CUA) and a point-mutant of yeast AspRS; derivatives of *Halobacterium* NRC-1 tRNA^{Leu} and *Methanobacterium thermoautotrophicum* LeuRS that result in suppression of *amber, opal* (UGA), and 4-base (AGGA) codons; and a consensus-derived archaeal tRNA^{Glu}(CUA) and *Pyrococcus horikoshii* GluRS. However, there has been no success in altering the amino acid specificity of any of these synthetases. Recently a mutant *Pyrococcus horikoshii* LysRS derivative has been selected for the incorporation of homoglutamine in *E. coli* in response to the four-base codon AGGA using a consensus-derived archaeal tRNA^{Lys}(UCCU). This is only the second orthogonal pair shown to be useful for unnatural amino acid incorporation in *E. coli*, and the fact that it allows four-base suppression means that it is now possible to simultaneously, site specifically introduce two unnatural amino acids into proteins.

2.2 Methods for Evolving Synthetases with Unnatural Amino Acid Specificity in *E. coli*

Once an orthogonal tRNA-synthetase pair has been developed for use in *E. coli*, the next step is the modification of the synthetase specificity such that it aminoacylates the orthogonal tRNA with a desired unnatural amino acid and no other endogenous amino acid.

This problem is complicated considerably by at least five factors. (1) The small amino acid substrates are contacted by a large number of residues concentrated in three-dimensional space but often spread over the primary structure of the synthetase. This makes it technically difficult to construct reasonable mutagenic libraries. (2) In spite of this, mutations far from the active site of aaRSs are known to affect aminoacylation kinetics. (3) Mutations to the synthetase can also affect recognition of tRNA, thereby altering the orthogonality of the enzyme. (4) It is extremely difficult to alter the specificity of an aaRS without reducing its aminoacylation activity, but a certain level of activity is required to support high-level protein synthesis. Thus, the engineering of synthetases with weak aminoacylation activity toward native substrates has proven to be exceedingly difficult. (5) Selecting for unnatural amino acid specificity requires that the survival of the organism be tied to the insertion of an unnatural amino acid, and no direct way to do this has been developed.

A small number of attempts have been made to alter the specificity of aaRSs by inspection or semiempirically, with varying results. For example, from genetic screens, it was known that the *Ec*PheRS Ala294 → Ser mutant resisted incorporation of *p*-F-Phe. Ibba and Hennecke showed that

the Ala294 → Gly mutant of this enzyme, with an expanded binding pocket, is capable of inserting *p*-Cl-Phe and *p*-Br-Phe, and the Tirrell group has shown that *para*-iodo, azido-, cyano-, and ethynyl-Phe are also accepted. Furter used the associated *p*-F-Phe resistant *E. coli* strain to engineer the first bacterium able to site-selectively insert an unnatural amino acid by introducing a *Sc*PheRS/*Sc*tRNA^{Phe}(CUA) pair that accepts *p*-F-Phe. However, the *Ec*PheRS(A294S) accepts *p*-F-Phe weakly,

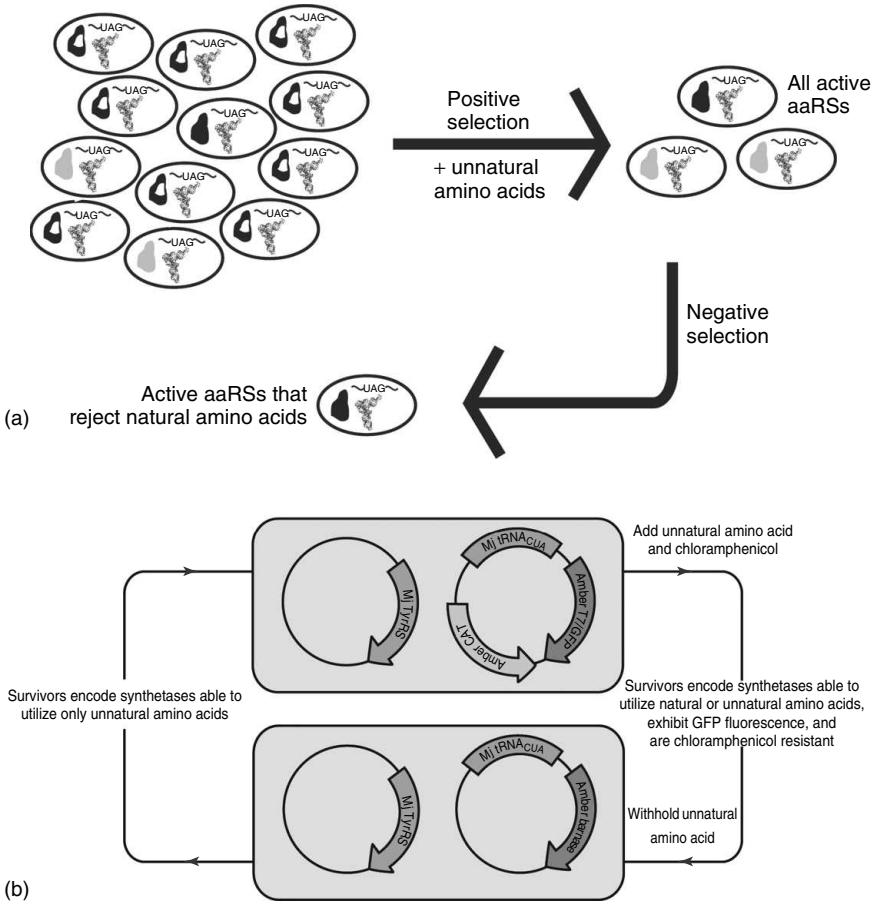

Fig. 2 ''Double-sieve'' selections for unnatural amino acid activity: (a) Schematic of a generic double-sieve selection. A library of orthogonal aminoacyl-tRNA synthetases is transformed into cells with an orthogonal tRNA. First, positive selection is done in the presence of unnatural amino acids, such that the selective phenotype requires acylation of the orthogonal tRNA and suppression of the unique codon. Cell with inactive synthetases (white) die, but those with synthetases active toward natural (grey) or unnatural (black) amino acids survive. Second, a negative selection is carried out in the absence of unnatural amino acid, where the selective phenotype requires that the tRNA *not* be acylated. Only cells with synthetases that lack activity toward natural amino acids survive. Thus, survival of both selections implies activity only toward unnatural amino acids. (b): A double-sieve selection in *E. coli*. (c): A double-sieve selection in yeast. (See color plate p. xxvi.)

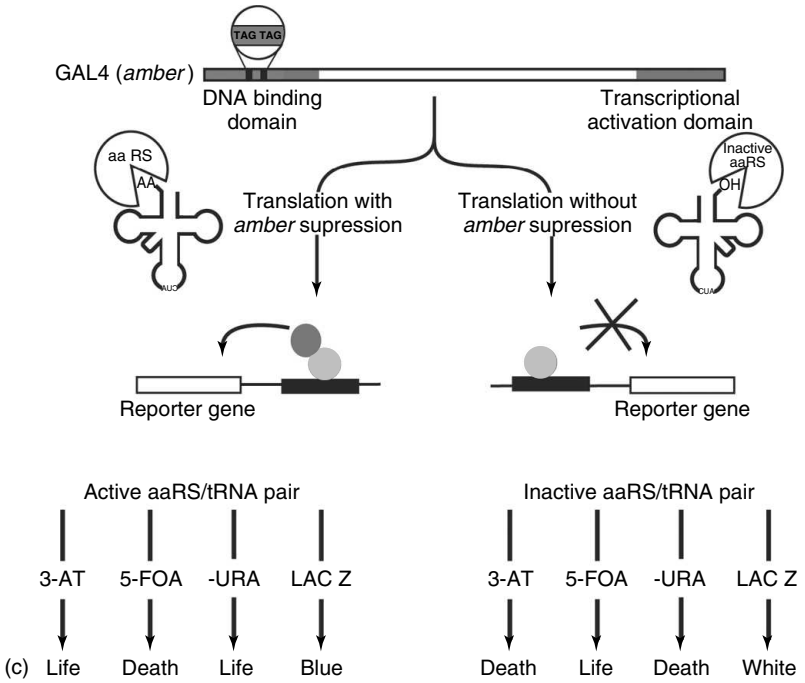

Fig. 2 (*Continued*)

and the *Sc*tRNA^{Phe}(CUA) is also acylated with Phe and Lys (presumably by *Ec*LyrsRS, in the latter case). Kiga et al. converted *Ec*TyrRS into an enzyme capable of accepting 3-iodotyrosine (3-I-Tyr) as a substrate by selecting three sites for mutagenesis based on structure, and examining the aminoacylation properties of 50 mutants *in vitro*. Interestingly, while >95% of *amber*-encoded sites were occupied by 3-I-Tyr in a wheat-germ extract translation reaction, Tyr-containing protein was produced if 3-I-Tyr was left out of the reaction mixture. This is potentially a problem when moving this technology into cells, since the concentration of unnatural amino acid cannot be controlled arbitrarily. A number of attempts have been made to change GlnRS into GluRS, but the resulting enzymes still prefer Gln (although by a considerably smaller amount than wild-type GlnRS). Additionally, some attempts to computationally predict mutations to alter amino acid specificity have been reported.

By far the most successful and general method for altering the specificity of aminoacyl-tRNA synthetases has been directed combinatorial mutagenesis of the amino acid binding pocket of synthetase enzymes coupled to a general ''double-sieve'' selection (see Fig. 2). Several general methods have been developed to alter the specificity of orthogonal aminoacyl-tRNA synthetase/tRNA(CUA) pairs that function in *E. coli* so that they use only a desired unnatural amino acid.

The selection of a library of aaRS variants was first carried out by a two-step procedure. In the first step, the library of synthetases is selected in bacteria bearing tRNA(CUA) and an *amber* mutant

of β-lactamase, with ampicillin and unnatural amino acid supplementation of the medium. Use of a permissive site in β-lactamase ensures that survivors of the selection contain aaRSs that are capable of acylating the tRNA(CUA) – thus producing β-lactamase and conferring resistance to ampicillin – but which amino acid was esterified onto the tRNA is unknown. The synthetases from the survivors of this positive selection are then expressed in bacteria bearing the tRNA(CUA) and a barnase gene containing multiple amber codons (wild-type barnase is a lethal ribonuclease in *E. coli*). No unnatural amino acids are added to the medium, so survival at this stage ensures that no cellular amino acids (proteinogenic or otherwise) are a substrate for the mutant synthetases. Clones that survive *both* steps of the selection should therefore be active *only* toward the unnatural amino acid. The initial implementation of this strategy (with the *Sc*GlnRS/*Sc*tRNA^{Gln}(CUA) orthogonal pair, a large library of mostly commercially available amino acids, and synthetase libraries created by random mutation) resulted in no useful synthetases.

Two critical technical improvements to the methodology were (1) the replacement of the β-lactamase positive selection with a chloramphenicol acetyltransferase-based selection, and (2) use of a directed, semirational library-construction method. Chloramphenicol is bacteriostatic and acts cytosolically, allowing a broad range of chloramphenicol concentration to be suitable for selection. Random mutagenesis of wild-type GlnRS had two negative consequences. First, most of the library members were very active toward Gln, requiring exceptional performance from the negative selection. Second, the probability of mutation in the proximity of the amino acid substrate was low. Instead, guided by the ternary X-ray crystal structure of *Ec*GlnRS, tRNA^{Gln}, and a Gln-AMP analog, 5–10 residues proximal to the substrate were first mutated to Ala and then randomized to all 20 amino acids. The resulting libraries contained few synthetases with activity toward Gln, allowing one to forego the negative selection in early rounds, and were almost certain to have an altered amino acid binding pocket.

Unfortunately, libraries designed for use with carboxamide N-alkylated Gln analogs, analogs elaborated from the γ-carbon, and the α-hydroxy acid analog of Gln were not found to contain any synthetases capable of activating the unnatural amino acids at useful levels. However, using the very same library construction and selection methodology, it has been possible to alter the specificity of *Mj*TyrRS and *Ph*KRS, allowing the delivery of several useful unnatural amino acids (see section 4 and Fig. 4). Santoro et al. extended the selection technology by developing a fluorescence-based screen for *amber* suppression. An *amber* mutant of T7 RNA polymerase was used to drive the transcription of green fluorescent protein (GFP). In combination with fluorescence-activated cell sorting (FACS), this system can be used as both a positive screen for *amber* suppression (where one sorts for fluorescent cells in the presence of unnatural amino acids) and a negative screen against *amber* suppression (sorting for dim cells in the absence of unnatural amino acids). A multivalent system, where chloramphenicol-based selection is possible in addition to screening, has been especially effective.

The fidelity of incorporation of each amino acid was established by several methods. First the clones were characterized by their ability to confer chloramphenicol resistance on cells transformed

with the CAT(*amber*) reporter in the presence and absence of a particular unnatural amino acid. In all successful cases, the IC_{50} values with respect to chloramphenicol were large (100 μg mL^{-1}) in the presence of unnatural amino acid, and were generally less than 10 μg mL^{-1} in the absence of the unnatural amino acid. Similarly, cellular fluorescence can be measured with the T7/GFP system in the presence and absence of unnatural amino acid.

Expression of *amber* mutants of DHFR, myoglobin, and the Z-domain of protein A was also directly assessed. In the presence of unnatural amino acid, synthetase, and tRNA, milligrams of each protein could be purified from a liter of liquid culture. Yields were typically 25 to 30% of wild-type protein. In the absence of any one component synthetase, tRNA, or amino acid, no protein could be observed by Western blot, silver stain, or Coomassie stain. Proteins were subjected to mass analysis of intact protein, and tryptic digests confirmed that the unnatural amino acid and only this amino acid is incorporated in response to the UAG codon and at no other site in the protein.

It is likely that the high activity of the *Mj*TyrRS and the excellent orthogonality of the synthetase and tRNA account for the malleability of this enzyme's substrate specificity. Though all of the libraries of *Mj*TyrRS were designed using the *Bacillus stearothermophilus* structure, the structure of the *M. jannaschii* protein has recently been solved. There are a number of differences in the tyrosine binding pocket that will improve further library design with the enzyme, and may even suggest ways to improve some of the existing mutant synthetases (see Fig. 3).

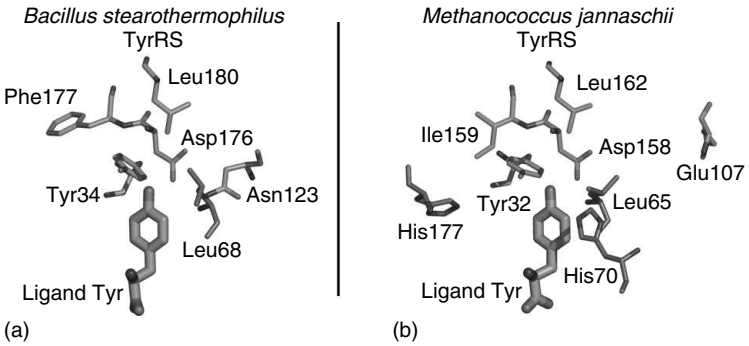

Fig. 3 The active site of TyrRS: Amino acids near the substrate tyrosine of (a) *Bacillus stearothermophilus* and (b) *Manococcus jannaschii* TyrRS. The Bacillus structure is a good model for the *Ec*TyrRS used to expand the genetic code of yeast. All the *Ec*TyrRS variants for the insertion of unnatural amino acids were derived from variants of Tyr37 (Tyr34), Asn126 (Asn123), Asp182 (Asp176), Phe183 (Phe177) and Leu186 (Leu180), where the corresponding amino acids in *Bs*TyrRS are noted parenthetically. Nearly all of the *Mj*TyrRS derivatives used for insertion of unnatural amino acids in *Escherichia coli* were generated by randomization of the Tyr32 (Tyr34), Glu107 (Asn123), Asp158 (Asp176), Ile159 (Phe177), and Leu162 (Leu180). These amino acids were selected from the *Bs*TyrRS structure, which was available at the time, but the recent *Mj*TyrRS structure suggests some possible improvements. Rendered using PyMOL (Warren Delano, 2002, http://www.pymol.org) from PDB entries 4TS1 and 1J1U.

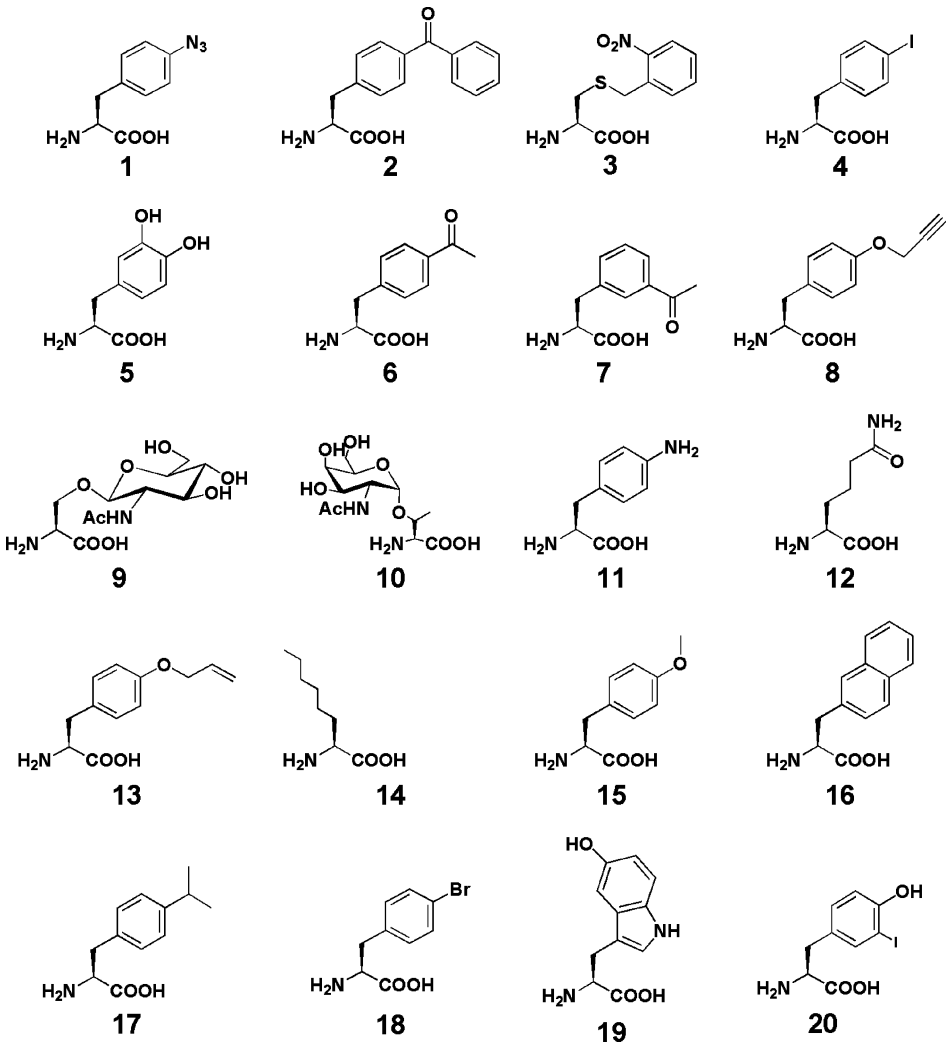

Fig. 4 Unnatural amino acids incorporated site specifically in living cells with modified aminoacyl-tRNA synthetases:

(20) *m*-iodo-L-tyrosine.

3
Expanding the Genetic Code of Eukaryotic Cells

3.1
Stoichiometric Aminoacylation Methods

The first expansion of a cell's genetic code was performed in *Xenopus* oocytes by microinjection of a chemically misacylated *Tetrahymena thermophila* tRNA(CUA), and a mutant mRNA containing the *amber* nonsense codon. An advantage of this approach, shared with the *in vitro* incorporation methods from which it is derived, is that the chemical groups that can be incorporated are constrained only by the translational machinery of the cell (which is highly permissive to a variety of amino acids with altered side chains) and by the chemistry of aminoacylation. This methodology allowed the detailed biophysical study of the nicotinic acetylcholine receptor in oocytes by the introduction of amino acids containing side chains with unique physical or chemical properties and the study their effect using patch clamp methods. A disadvantage of this approach for studying other cellular proteins is that it is not applicable to producing mutant versions of many proteins at their normal *in vivo* levels or for producing enough protein to assay using standard cell biological approaches.

Recent extensions of this approach have extended the type of eukaryotic cell that it can be used to study, by altering the method of delivery of chemically acylated tRNAs and mRNA. It has been shown that chemically aminoacylated tRNAs can be electroporated or transfected into mammalian cells (including neurons) in culture. Again, since the tRNA cannot be re-acylated *in vivo*, the yield of protein produced is very low and this potentially limits the range of cellular processes that these methods can be used to study.

3.2
Catalytic Aminoacylation Methods

There has been considerable interest in extending the principles for expanding the genetic code of bacteria to eukaryotic cells. This would have significant technical and practical advantages over stoichiometric incorporation methods, since tRNAs would be acylated by their cognate synthetases, leading to large amounts of mutant protein. Moreover, genetically encoded aminoacyl-tRNA synthetases and tRNAs are, in principle, heritable, allowing the unnatural amino acid to be incorporated into proteins through many cell divisions without exponential dilution.

The steps necessary to add new amino acids to the genetic code of *E. coli* have been described; similar principles are likely to be useful for expanding the genetic code of eukaryotes. However, because the cellular tRNAs and aminoacyl-tRNA synthetases are not well conserved between prokaryotes and eukaryotes, the translational components from *M. janaschii* added to *E. coli* are not orthogonal in eukaryotic cells. The challenges in extending this approach are therefore to discover new orthogonal pairs in which the tRNA is produced in a functional form *in vivo*, to devise selection methods for altering the specificity of the orthogonal synthetase, and to create large libraries of mutant synthetases in a eukaryotic cell.

3.3
Orthogonal Aminoacyl-tRNA Synthetase/tRNA Pairs in Eukaryotic Cells

The orthogonal pairs reported to date for eukaryotes are derived from bacterial

pairs. This reflects the fact that the divergence of identity elements of tRNAs from prokaryotes to eukaryotes is greater than that from eukaryotes and archea and between one eukaryote and another. However, it is clear that in some instances bacterial tRNA cannot simply be cut and pasted into eukaryotic cells. In eukaryotes, the synthesis of tRNAs is dependent on RNA Polymerase III and its associated factors, which recognize A and B box sequences that are internal to the tRNA structural gene (''internal promoters''). The A and B box consensus sequences place limitations on the tRNA sequences that can be used in eukaryotic cells, and some bacterial tRNAs that diverge from the eukaryotic A and B box sequence are simply not transcribed in eukaryotic cells. Moreover, many eukaryotic tRNAs have the 3′ CCA sequence added enzymatically by CCA transferase, while all *E. coli* tRNAs encode this sequence in the DNA sequence, and it may be necessary to delete the 3′ CCA in the *tRNA* gene imported from *E. coli*. The processing or transcription of a tRNA appears, in some cases, to require organism-specific flanking sequences 5′ and 3′ to the tRNA gene. Posttranscriptional nucleotide modifications, that may be absent in the host eukaryote, may also be necessary to produce a functional tRNA molecule. In addition, since the tRNA is transcribed in the nucleus, it must be exported to the cytoplasm to function in translation via an exportin-dependent process. Nonetheless, several potential orthogonal pairs have been described in eukaryotes.

E. coli tyrosyl-tRNA(CUA) can be expressed and correctly processed, as judged by Northern blot, in *S. cerevisiae* when the flanking sequences 5′ and 3′ to the structural gene are included and the 3′ flanking sequence is altered to a poly T stretch to allow Pol III transcriptional termination. To demonstrate the functionality and orthogonality of *E. coli* tyrosyl-tRNA(CUA) in yeast, a reporter strain was constructed that contained three auxotrophic *amber*-suppressible alleles, allowing qualitative comparison of *amber* suppression on media lacking methionine, tryptophan, or histidine. When this strain was transformed with a plasmid containing the *E. coli* tRNA(CUA) at a variety of copy numbers, all transformants were MET^{-} HIS^{-} TRP^{-}, indicating that any aminoacylation of this tRNA by yeast cytoplasmic synthetases was at a low level. When the same yeast strain was cotransformed with plasmids encoding the *E. coli* tRNA(CUA) and its cognate synthetase, suppression of all three alleles was observed, and shown to be correlated with the expression level of the tRNA. These experiments demonstrated that *E. coli* tyrosyl-tRNA is orthogonal in *S. cerevisiae,* and can be aminoacylated by its cognate synthetase. Numerous *in vitro* experiments have demonstrated that *E. coli* tyrosyl-tRNA synthetase does not aminoacylate total *S. cerevisiae* tRNA. Thus, the *E. coli* tyrosyl-tRNA synthetase/tRNA pair is a candidate orthogonal pair. Two other orthogonal pairs have subsequently been reported for *S. cerevisiae*. One is derived from *E. coli* glutamine-tRNA synthetase and an amber suppressor derived from human initiator tRNA while the other is derived from an *E. coli* leucine pair. Thus far the tyrosine and leucine orthogonal pairs form *E. coli* have been used to expand the genetic code of *S. cerevisiae*.

There have also been efforts to create orthogonal pairs in higher eukaryotic cells. A derivative of the *E. coli* glutamine pair is orthogonal and functional in mammalian cells. The tRNA of this pair, a variant of *E. coli* $tRNA^{Gln}$(CUA), was created by replacing C9 in the bacterial tRNA with the

mammalian A box consensus base A9, and the native flanking sequences were replaced with those of the human initiator tRNA. These changes were shown to drastically increase the transcription of the tRNA in a HeLa cell-free system. When COS-1 cells were transformed with a CAT reporter containing an amber codon at a permissive site, a $tRNA^{Gln}$(CUA) gene driven to high copy on an SV40-based vector and an *Ec*GlnRS gene, *amber* suppression was observed in a CAT assay. CAT activity was dependent on the presence of all three components. Since *Ec*GlnRS does not charge total mammalian tRNA, the *Ec*GlnRS/tRNA(CUA) constitute an orthogonal pair in mammalian cells. However, the amount of suppression observed with this pair was much lower than observed for a human serine amber suppressor, suggesting that this synthetase/tRNA pair is far from optimal. Yokoyama and coworkers have subsequently investigated bacterial tyrosyl-tRNA synthetase tRNA(CUA) pairs for their potential as orthogonal pairs in mammalian cells. These experiments showed that *E. coli* tyrosyl synthetase/*Bst*tRNA(CUA) form a potential orthogonal pair in mammalian cells. The efficiency of this pair appears to be good, with Ras yields from an amber mutant of the *ras* gene being about 25% of those from the wild-type *ras* gene in the same system. The synthetase of this pair has subsequently been altered to allow the incorporation of numerous unnatural amino acids in mammalian cells (see the following). In addition, it has subsequently been shown that the tryptophanyl synthetase and cognate opal suppressor derived from *B. subtilis* are orthogonal in mammalian cells. The efficiency of the pair appears to be comparable to the *E. coli* tyrosine pair and it was used to incorporate an unnatural amino acid in mammalian cells.

3.4 Methods for Evolving Synthetases with Unnatural Amino Acid Specificity in Eukaryotic Cells

With an orthogonal aminoacyl-tRNA synthetase that aminoacylates the orthogonal suppressor tRNA in hand, a method is required to alter the specificity of the aminoacyl-tRNA synthetase so that it aminoacylates its cognate tRNA, and only its cognate tRNA with desired unnatural amino acid and no endogenous amino acid present in a eukaryotic cell.

The first approach to this problem was to screen a small number of active site variants. Using this method, Yokoyama and coworkers evaluated a small collection of *Ec*TyrRS mutants in an *in vitro* wheat-germ translation system and discovered an *Ec*TyrRS variant that utilizes 3-iodotyrosine more effectively than tyrosine. However, this enzyme still incorporates tyrosine in the absence of the unnatural amino acid. More recently, Yokoyama and coworkers have also demonstrated that this *Ec*TyrRS mutant functions with a tRNA(CUA) from *B. stearothermophilus* (see preceding text for a discussion of this orthogonal pair) to suppress *amber* codons in mammalian cells. The fidelity of incorporation was shown by LC-MS to be greater than 95%. A similar approach was subsequently used to discover mutants of the orthogonal *B. subtilis* TrpRS/tRNA(UCA) that incorporate 5-hydroxy-L-tryptophan (5-HTPP). On the basis of the crystal structure of the homologous enzyme from *B. stearothermus*, Val144 that points toward C5 of bound tryptophan adenylate was mutated to all other 19 amino acids. One mutant Val144 → Pro was able to suppress a TGA codon placed in the *foldon* gene in the presence of 5-HTPP. Moreover, in the absence of the unnatural

amino acid, no full-length Foldon protein was synthesized, suggesting the mutant synthetase is specific for 5-HTPP. Mass spectrometry confirmed the incorporation with a fidelity >97%.

To add numerous unnatural amino acids to the genetic code of eukaryotic cells, Chin et al. developed a general, *in vivo* selection method for the discovery of variants of *Ec*TyrRS/tRNA(CUA) or other orthogonal pairs that function in yeast to incorporate unnatural amino acids, but no endogenous amino acids, in response to the *amber* codon UAG. A major advantage of a selection is that enzymes that incorporate unnatural amino acids can be rapidly selected and enriched from libraries of 10^8 *Ec*TyrRS active site variants, 6 to 7 orders of magnitude more diverse than can be easily screened *in vitro*. This increase in diversity vastly increases the likelihood of isolating *Ec*TyrRS variants for the incorporation of a diverse range of useful functionality with very high fidelity.

A key to the selection was a strain of *S. cerevisiae*, MaV203:pGADGAL4 (2TAG) (see Fig. 2), that contains a plasmid encoded gene for the transcriptional activator protein GAL4 in which the codons for Thr44 and Arg110 (for which substitution with numerous other amino acids has minimal effects on GAL4 activity) were converted to amber nonsense codons. Suppression of these amber codons leads to the production of full-length GAL4, which in turn leads to transcriptional activation of genomic GAL4 responsive *HIS3*, *URA3*, and *LACZ* reporter genes. Expression of *HIS3* and *URA3* complement the histidine and uracil auxotrophy in this strain, allowing clones expressing active aaRS/tRNA pairs to be selected. Upon addition of 5-fluoroorotic acid (5-FOA), which is converted to a toxic product by the URA3 protein, clones expressing inactive aaRS/tRNA pairs can be selected. The *lacZ* reporter allows active and inactive synthetase/tRNA pairs to be discriminated colorimetrically. Thus, a single strain of *S. cerevisiae* can be used for positive and negative selections, minimizing the number of manipulations necessary to identify aaRS/$tRNA_{CUA}$ pairs that use unnatural amino acids.

To use this selection method to expand the eukaryotic genetic code, a library of EcTyrRS mutants was generated. On the basis of the crystal structure of the homologous *Bs*TyRS in complex with tyrosine, five residues within 7 Å of the *para* position of the bound tyrosine were randomly mutated to all amino acids, and the library was transformed into the selection strain yielding 10^8 transformants. To select for cells containing mutant synthetases that selectively aminoacylate the orthogonal *E. coli* tRNA(CUA), a two-step selection was carried out. In the first step, a positive selection for cells able to grow on media lacking uracil or containing 20 mM 3-aminotriazole (3-AT, a competitive inhibitor of the HIS3 protein) in the absence of histidine was performed. If a mutant TyrRS charges tRNA(CUA) with an amino acid, then the cell biosynthesizes histidine and uracil and survives. In a second step aimed at removing clones that incorporate endogenous amino acids in response to an amber codon, a negative selection was applied. Cells were grown on media containing 0.1% 5-FOA, but lacking the unnatural amino acid. Those cells expressing URA3, as a result of suppression of the GAL4 amber mutations with natural amino acids, convert 5-FOA to a toxic product and cause cell death. Surviving clones were amplified in the presence of unnatural amino acid and reapplied to the positive selection. Synthetases for the incorporation of numerous unnatural

amino acids have been developed through this method.

The specificity and activity of each mutant synthetase/tRNA pair was tested in several ways. First, individual clones were tested for the ability to confer survival on MaV203:pGADGAL4 on – Ura or – His +20 mM 3-AT in the presence and absence of an unnatural amino acid, and the blue/white phenotype was tested on X-Gal in the presence and absence of the amino acid. Clones that grow on selective media and turn blue on X-Gal only in the presence of the unnatural amino acid were selected for further characterization. Second, an amber mutant of hexahistidine tagged human superoxide dismutase (SOD) was overexpressed in the presence of each synthetase/tRNA pair with and without cognate unnatural amino acid (see Fig. 5). In the presence of the unnatural amino acid, SOD-His_6 was produced, but in the absence of added amino acid no SOD could be purified. Moreover, the SOD purified from yeast cell growth in the presence of each unnatural amino acid was shown, by mass spectrometry, to contain the desired unnatural amino acid at the desired position with fidelity in excess of 99.9%. The total yield of purified SOD was about 20% of that produced from the analogous wild-type *SOD* gene.

Synthetases evolved in yeast can be readily transplanted to higher eukaryotes when paired with a functional cognate orthogonal tRNA for the higher organism. Using this strategy, the unnatural amino acid dependent synthetases evolved in yeast have been transplanted into mammalian cells, along with the cognate amber-suppressor tRNA derived from *B. stearothermophilus*, and incorporation of each unnatural amino acid demonstrated.

4 Using Expanded Genetic Codes

4.1 The Utility of Expanded Genetic Codes

Several applications of expanded genetic codes have been demonstrated. Numerous future applications can be predicted from applications that have been achieved with other methods including the *in vitro* incorporation of amino acids, multisite amino acid–incorporation, and expressed protein ligation. Perhaps even more exciting are the entirely novel applications that are beginning to emerge, in which *in vivo* incorporation of unnatural amino

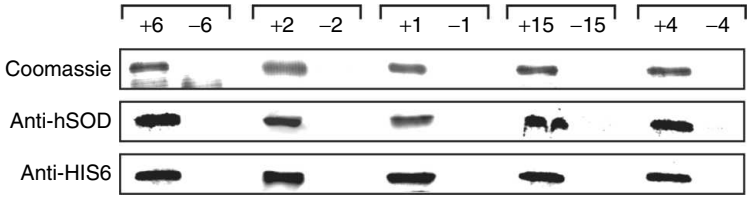

Fig. 5 Unnatural amino acid dependent protein expression in yeast: An *hSOD* gene containing an amber codon at position 33 was used to produce protein in yeast strains with aminoacyl-tRNA synthetase/tRNA pairs for specific amino acids (see Fig. 4). HSOD was purified from yeast in the presence (+) and absence (–) of the unnatural amino acid indicated and SOD expression was visualized by Coomassie stain or Western blot using antibodies against hSOD and the C-terminal hexahistidine tag.

acids are used to interrogate processes inside living cells with molecular precision. Here we focus on the utility of the expanded genetic code in *E. coli* using pairs derived from *Mj*TyrRS/tRNA(CUA) or in yeast using the *Ec*TyrRS/tRNA(CUA) pair or EcLeuRS/tRNA(CUA).

4.2 Biophysical Probes

Aryl iodides have been site specifically incorporated into proteins in both *E. coli* and yeast, and have subsequently been used for X-ray structure determination via single wavelength anomalous diffraction on a home X-ray source. The method appears to require significantly less data than selenomethionine incorporation. Both *p*-benzoyl-phenylalanine and *p*-azido-phenylalanine have been incorporated into proteins in bacteria and yeast (see Fig. 6). These amino acids allow photoaffinity labeling of interacting proteins upon irradiation at 360 nm. The covalently linked proteins can then be isolated or visualized electrophoretically after *in vitro* or *in vivo* cross-linking. This utility of this method was demonstrated in a model system, and has subsequently been used to determine a binding site of a client protein on the chaperone ClpB. Isotopic labeling (e.g. ^{19}F) of unnatural amino acids should aid NMR structure determination. Other biophysical probes such as spin labels for EPR studies are likely future targets.

The genetic code of yeast has been expanded to include a nitrobenzyl cysteine. This photocaged cysteine can be deprotected, allowing the temporal control of protein function. Several unnatural amino acids have been useful for engineering chemical scission sites into proteins, though these have not yet been incorporated into proteins *in vivo*. Hydroxyacids inserted through chemical acylation of tRNA result in an ester linkage that can be cleaved in base. Similarly, specific cleavage at aminooxyacetic acid can be achieved with zinc and acetic acid, and cleavage of the protein backbone at allylglycine

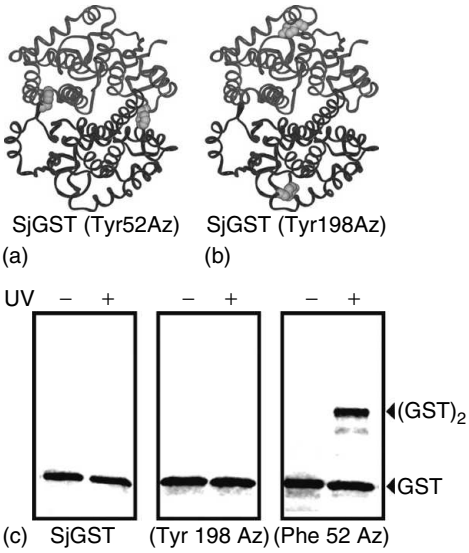

Fig. 6 An example of the utility of expanded genetic codes: *p*-azido-L-phenyalanine (1) is inserted into glutathionine-*S*-transferase at position 52 (a) or position 198 (b). On irradiation with UV light (c) the azido group photocross-links protein monomers in the dimeric GST complex. This cross-linking is dependent on the azido group being at the protein interface (position 52). Similar experiments have been used to map protein–protein interactions both *in vitro* and in cells. (See color plate p. xxv.)

is possible upon treatment with iodine. Photochemical proteolysis occurs upon irradiation at 2-nitrophenylglycines.

4.3 Unique Reactive Handles

Expanding the reactivity of proteins, particularly in a site-specific way, is a potentially useful alteration to proteins. Chemical modification of natural proteins is basically limited to use of the nucleophilic groups: cysteine's thiol, amines on lysine, and at the N terminus, histidine's imidazole, and the alcohols, depending upon pH. However, it is often difficult to prevent cross-reaction with other nucleophilic groups in the protein, and extensive mutation (for example, to yield a single-Cys version of a protein) is often required. It is possible to introduce an electrophile into a protein by mild oxidation of N-terminal serine or threonine, but more general approaches to unique reactive handles have many potential applications.

The genetic codes of *E. coli* and yeast have been expanded to include a ketone that allows the chemoselective formation of hydrazones and oximes using hydrazides and hydroxylamines respectively. Hydrazone formation is possible in living cells to label ketone-containing protein with fluorophore hydrazides. Both cytosolic and outer-membrane proteins have been labeled in this fashion. Ketones also allow for the possibility of protein stabilization by formation of an imine with lysine. The addition of an azides and alkynes to the genetic code of both *E. coli* and yeast allows site specific–protein derivatization via a Cu(I) catalyzed $3 + 2$ cycloaddition. This reaction has been used to specifically PEGylate proteins or to add biotin or fluoroscein groups. An alternative derivatization strategy for azides would involve a Staudinger-like ligation, which has been used to selectively modify sugar moieties on cell surfaces, in mice, and for the labeling of azidohomoalanine introduced into proteins using *in vivo* amino acid replacement.

4.4 Posttranslational Modifications

Understanding the roles of proteins in cellular function necessarily means understanding the extent and function of posttranslational modification, particularly in eukaryotes. However, it is difficult to obtain specifically, homogeneously modified protein. The genetic code of *E. coli* has been expanded for the incorporation of β-GlcNAc-serine, where proteins are not normally glycosylated, permitting homogeneous preparation of large amounts of glycoprotein. Expressed protein ligation has also been used to study posttranslational modifications via the synthesis of phosphorylated or nonhydrolyzable phosphorylation mimic amino acids, or via geranylgeranyl amino acids. It is likely that the expansion of the genetic code will allow the direct incorporation of these and other posttranslational modifications into proteins *in vivo*.

4.5 Organism Evolution

In all the above studies, the amino acid must be added to the growth medium and taken up by the cell in order to be incorporated into a protein in response to the *amber* codon. An alternative strategy is to engineer a pathway for the biosynthesis of the unnatural amino acid in the host organism. In this way, a completely autonomous bacterium has been generated that contains genes for the biosynthesis of *p*-amino-L-phenylalanine

(pAF) from simple carbon sources, an aminoacyl-tRNA synthetase that uses this new amino acid and no other endogenous amino acids, and a tRNA that delivers into proteins in response to the *amber* codon.

To biosynthesize pAF, the *papA*, *papB*, *papC* genes from *S. venezuelae* were imported into *E. coli*. The PapA protein, 4-amino-4-deoxychorismate, was expected to convert chorismate to 4-amino-4-deoxychorismic acid using ammonia from glutamine in a simple addition-elimination reaction. PapB should convert 4-amino-4-deoxychorismic acid to 4-amino-4-deoxyprephenic acid, and PapC should then convert 4-amino-4-deoxyprephenic acid to *p*-aminophenylpyruvic acid. The endogenous aminotransferases (*tyrB*, *asps*, *ilvE*) were expected to convert this to pAF. *E. coli* containing these genes were found to produce *p*-amino-L-phenylalanine at levels comparable to those of other aromatic amino acids and had normal growth rates. Cells producing *p*-amino-L-phenylalanine were able to incorporate it into myoglobin in response to an *amber* codon with high fidelity, as judged by mass spectrometry of the mutant protein and in high yield of 2 mg L^{-1} of culture. These yields are comparable to those observed when the unnatural amino acid is added to the growth media directly. In addition to *p*-amino-L-phenylalanine, it should be possible to biosynthesize and genetically encode other amino acids *in vivo* as well including methylated, acetylated, and glycosylated amino acids.

The creation of a 21 or 22 amino acid code removes a billion year constraint on the evolution of life, allowing the experimental assessment of the fitness of organisms with expanded genetic codes. By placing *amber*, *opal*, or four-base codons throughout the genome, we can compare the survival of various 20, 21, and 22 amino acid organisms in response to selective pressures. Some unnatural amino acids, such as ketones, expand the reactivity of proteins, permitting new mechanisms of stabilization (imines with lysine, for example) and new chemistries (ketones and aldehydes are found in cofactors but not among the natural amino acids). It will be interesting to see how nature can make use of these new reactivities in response to stresses like extremes of temperature of pH.

5 Summary

Expanding the natural repertoire of amino acids is creating a powerful set of tools for biochemical, biophysical, and cellular studies far beyond the possibilities afforded by site-directed mutagenesis. Engineering the biosynthetic machinery also tests our understanding of how organisms achieve fidelity in protein synthesis, and has resulted in some of the most profound changes in enzyme function attained by any method of protein engineering. However, it is still not possible to easily generate a synthetase with substrate specificity for any desired amino acid, and there is a strict limit on code expansion imposed by the small number of blanks in the genetic code from suppressible stop codons and 4-base codons. The development of further highly active and orthogonal tRNA/synthetase pairs and the development of unnatural codons will be major areas of effort in the upcoming decade.

Keywords

Exocytosis
Fusion of an intracellular organelle (usually a trafficking vesicle or a specialized secretory vesicle) with the plasma membrane. Exocytosis can be further subdivided into regulated and constitutive exocytosis. Examples for the former are neurotransmitter release by exocytosis of synaptic vesicles or hormone and enzyme release by secretion from exocrine and endocrine glands. Examples for the latter include the continuous incorporation of trafficking vesicles as required for receptor recycling and cell growth. For many years, neuronal exocytosis has served as a paradigm for studying the mechanisms of membrane fusion.

Fusion Peptides
Stretches of usually 20–60 amino acids that are part of viral fusion proteins and are thought to be inserted into the target membrane upon activation. Fusion peptides are amphiphilic, that is, when forming an α-helix one face contains hydrophobic/large-side chains whereas the rest of the surface is hydrophilic. Isolated fusion peptides insert into membranes, and several of them were shown to be potent fusogens, that is, they are capable of fusing membranes even without being attached to a protein.

Fusion Pore
The opening of an aqueous connection between the distal sides of the two fusing membranes. In a protein-mediated fusion, fusion pores are tight so that no leakage occurs between the distal and proximal sides of the fusing membranes. While fusion pores can be characterized with electrophysiological methods, the molecular structure of these intermediates in the fusion pathway is unknown. Both proteinaceous and lipidic intermediates are discussed.

Hemifusion
A hypothetical intermediate in bilayer fusion in which there is already a free exchange of membrane lipids, although an aqueous connection (fusion pore) is not yet formed.

SNAREs
A superfamily of small proteins (molecular weight between 10 and 35 kDa) that catalyze membrane fusion in the secretory pathway of eukaryotic cells. Each fusion step involves a specific set of SNAREs that spontaneously assemble into ternary or quaternary complexes, bridging the membrane and initiating fusion. After fusion, SNARE complexes are disassembled by the ATPase NSF (NEM-sensitive factor) in conjunction with cofactors termed SNAPs (soluble NSF attachment proteins).

Viral Fusion Proteins
Membrane proteins on the surface of enveloped viruses, that is, viruses that are surrounded by a phospholipid bilayer. Viral fusion proteins are metastable. Upon activation during cell contact or after endocytosis they undergo a spontaneous conformational change that mediates the fusion of the viral with the cell membrane, resulting in the injection of the nucleocapsid into the host cell cytoplasm. Viral fusion proteins are divided into class I and class II fusion proteins, which differ with respect to overall structure and fusion kinetics.

The fusion of biological membranes is one of the most fundamental reactions of life. It involves the initial recognition of the membranes, the close apposition of the membranes followed by the generation of nonbilayer intermediates, and finally the opening of an aqueous fusion pore. While the intermediates in various fusion reactions share common features, diverse classes of proteins evolved independently to carry out the task. Single proteins may be responsible for the entire reaction sequence as is the case for fusion proteins of enveloped viruses. In contrast, intracellular fusion reactions are mediated by cascades of reactions carried out by multiprotein complexes allowing for tight spatial and temporal regulation. Although the precise mechanism of fusion proteins is not yet fully understood, it is becoming clear that fusion proteins are nanomachines that exert mechanical force upon the membranes destined to fuse. Intriguingly, all characterized fusion proteins undergo major refolding during the reaction. Refolding proceeds downhill an energy gradient and yields highly stable oligomeric complexes with a stiff rodlike structure suggesting similarities in the fusion pathway.

1 Introduction and Overview

Membranes are fundamental to all forms of life. They form barriers that cannot be penetrated by hydrophilic molecules and that allow the enclosing of compartments containing biological macromolecules. Every cell is surrounded by a membrane that usually is represented by a bilayer of amphiphiles (phospholipids and related compounds). Furthermore, eukaryotic cells contain membrane-surrounded organelles.

Since the barrier function of membranes must be maintained at all times, special mechanisms that enable membranous compartments to merge or to split have been evolved. These mechanisms are referred to as *membrane fusion* and *membrane fission*. Both fusion and fission of biological membranes are characterized by specific features:

- no leakage occurs between the inside and the outside of the membrane-delineated spaces
- the asymmetry of the membrane is maintained, that is, amphiphiles do not randomize between the two monolayers
- they are mediated by specific proteins.

Biological membrane fusion events can be classified in

- extracellular fusions between cells, for example, sperm–egg fusion and fusions yielding polynucleated cells such as muscle cells or osteoclasts
- fusions of enveloped viruses with the plasma membrane of host cells
- intracellular fusions of and between organelles with the surrounding plasma membrane.

In recent years, significant progress has been made in identifying the proteins responsible for fusing biological membranes. Although there is still considerable debate about the precise role of many of these proteins, it has become clear that proteins capable of fusing membranes originated several times independently during evolution. Best understood are the fusion proteins of enveloped viruses. They fall into at least two major classes that are structurally unrelated to each other, and the diversity in either one of the classes is so great that even for these a common evolutionary origin is doubtful. Eukaryotic cells contain at least three classes of fusion proteins: those involved in extracellular fusions whose identities are largely unknown, those involved in the homotypic fusion of mitochondria, and finally those involved in fusion events of the so-called secretory pathway.

2 Physical Principles of Bilayer Fusion

Membranes are typically organized in bilayers composed of two leaflets of amphiphilic molecules such as phospholipids. These molecules have an elongated shape, with a hydrophilic head group and a hydrophobic tail that is often composed of hydrocarbon chains. The hydrophilic groups are exposed to the aqueous environment, whereas the hydrophobic tails face the hydrophobic interior of the bilayer.

Membrane fusion first requires that the two membranes destined to fuse be brought into close contact, requiring that electrostatic and hydration repulsion is overcome. Next, transition states that locally disrupt the bilayer structure must be generated, involving both hydrophilic and hydrophobic contacts between the membrane constituents. These transition states are governed by the hydrophobic effect, that is, by forces that minimize the exposure of hydrophobic surfaces to water. Finally, the bilayer structure is reinstated, which is associated with the local opening of an aqueous fusion pore.

Fusion sites are ''dirty nanostructures'' in that they have a variable composition involving hundreds of amphiphiles but with a size too small for resolving them with a light microscope. Furthermore, they dynamically change during the reaction, and it is not easy to arrest the fusion reaction at a defined intermediate state. Thus, the structure of the nonbilayer transition states cannot be directly determined. However, both theoretical and experimental approaches have led to well-founded models that describe the steps involved in membrane fusion in accordance with physical principles. The most widely accepted model is referred to as *stalk hypothesis* (Fig. 1). In its original version, the stalk hypothesis is based on macroscopic physics (continuum models) and describes the energy landscape of the fusion pathway on the basis of parameters such as bending energy, intrinsic curvature of the lipids, tilt of hydrocarbon chains, and it takes into account energy penalties due to the presence of hydrophobic voids in the

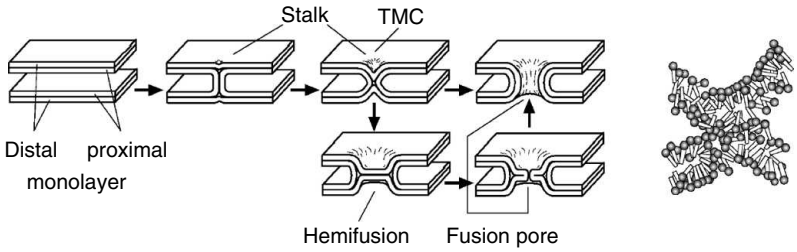

Fig. 1 Transition states in membrane fusion according to the stalk hypothesis. The monolayers are shown as smooth and bendable sheets. TMC, transmembrane contact. On the right, a snapshot of a nonbilayer intermediate is shown that is derived from a simulation of membrane fusion using simplified (coarse-grain) models for membrane lipids. Reprinted from Jahn, R., Lang, T., Südhof, T.C. (2003) Membrane fusion, *Cell* **112**, 519–533.

nonbilayer transition states. According to this hypothesis, the first steps involve the merger of proximal monolayers, a process that may be facilitated by thermal motions of individual amphiphiles perpendicular to the membrane plane. As a result, a fusion stalk is formed, followed by a symmetrical structure in which the first contact between the distal monolayers is established, which is also referred to as transmembrane contact (TMC). From this intermediate, a fusion pore may directly form or else, a hemifusion diaphragm is formed in which the contact zone of the distal monolayers expands, with a fusion pore forming at a later state (Fig. 1).

A large body of experimental evidence supports the overall description by the stalk hypothesis of the fusion pathway. For instance, structures similar to the intermediate involving the first TMC (Fig. 1) have been observed by X-ray diffraction in stacks of dehydrated bilayers. Similarly, such structures are part of the so-called rhombohedral/hexagonal phase of certain membrane lipids. Furthermore, addition of amphiphiles, which promotes either positive or negative curvature promotes or inhibits progression through the transition states as predicted by the model, and in many fusion events lipid mixing is observable before an aqueous connection is formed. However, the structure and precise orientation of the membrane lipids during the transition states is not known, and it has not been possible to show directly that stalks are intermediates of biological fusion reactions. Recent efforts to simulate membrane fusion using coarse-grain models also resulted in stalk-like intermediates, but the transition states appeared to be more disordered than originally assumed by the stalk hypothesis. While these models presently suffer from an arbitrary choice of fitting parameters, it is hoped that full atomistic simulations using refined force fields will yield more realistic and less biased structural models of fusion intermediates.

Unless strained or otherwise destabilized, membranes do not spontaneously fuse with each other under normal conditions (ambient temperature and pressure). However, amphiphilic molecules such as polyethylene glycol or certain amphipatic peptides can mediate spontaneous fusion of membranes. Similarly, certain amphipatic proteins (e.g. annexins) induce fusion of artificial membranes although there is no evidence that they act as fusion

proteins in their native environment. Apparently, the activation energy barrier for membrane fusion is not very high, requiring less specificity for the catalyst than, for example, an enzyme-catalyzed metabolite conversion.

3 Transition States of Protein-mediated Fusion and Fusion Pores

In the 1980s, two models were proposed explaining how proteins may mediate fusion. They describe two possible extreme situations that are instructive and that are still widely used as reference (Fig. 2). The first model describes the initial steps of fusion analogous to the formation and activation of gap junction channels. Each membrane contains oligomeric fusion proteins that assemble into a closed, ringlike oligomeric structure. Upon membrane contact, these rings connect and form an aqueous channel that represents the first opening of the fusion pore. Capacitance patch-clamping experiments revealed that fusion pores with an initial diameter of about 2 to 5 nm may reversibly open and close at a millisecond timescale (''flickering''), supporting the view that fusion pores, at least in their initial state, resemble channel proteins. Subsequently, both the oligomeric assembly and the TMC need to be broken up in order for the fusion pore to expand and for fusion to be completed. According to this model, the initial states of fusion including the transition states are primarily governed by protein–protein interactions and subsequently by protein–lipid interactions.

The second model assumes that the role of proteins in fusion is confined to providing a scaffold that lowers the activation energy barrier, while the transition states and the initial fusion pore is exclusively lipidic and thus must be in accordance with lipid biophysics. Accordingly, there is no need for the proteins to span the membrane. Rather, the role of fusion proteins may be

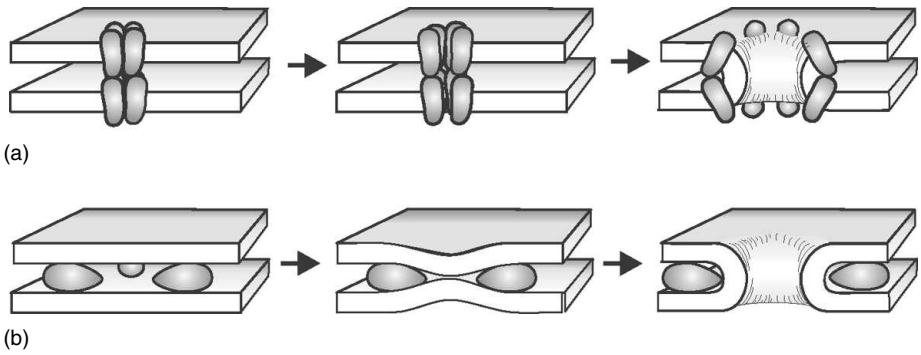

Fig. 2 Classical models for protein-mediated membrane fusion. (a) Channel-model. Here, the fusion proteins form a closed channel that connects in ''trans,'' resulting in a tight connection between the two membranes that is reminiscent of gap junctions. Formation of a fusion pore is due to the opening of a proteinaceous channel. Enlargement is mediated by lipid invasion between the dissociating subunits. (b) Scaffold model. Here, the role of the proteins is confined to bending of the membrane (in the original version it was assumed that a dimple is created in one of the membranes), with all transition states governed by lipid biophysics.

confined to forming a tight connection between the membranes, or else, they may destabilize the hydrophilic–hydrophobic boundary of the membrane to facilitate nonbilayer transition states. Fusion pore flickering, originally considered to be a hallmark of protein-mediated fusion, was later also observed in fusion events of protein-free artificial membranes, thus depriving the ''channel'' model of one of its strongest supportive arguments.

As discussed in more detail below, it is still unknown which of the two models is more accurate. Furthermore, the hypothesis that different classes of fusion proteins operate by different mechanisms cannot be excluded. While most investigators agree that lipids play a major role in the early transition states as suggested by the scaffold model, modifications of fusion proteins were reported to directly affect fusion pore characteristics indicating that fusion proteins do more than just clamping membranes together.

4 Viral Fusion Proteins

Enveloped viruses are enclosed by a host cell–derived bilayer that protects the nucleocapsid containing the viral genome. In order to infect cells, the viral membrane needs to fuse with the host cell membrane, resulting in the delivery of the nucleocapsid into the cytoplasm of the host cell. For this task, enveloped viruses contain specific membrane proteins whose purpose is to execute the fusion of the viral with the host cell membrane. Viral fusion proteins can be divided into class I and class II proteins, with class I proteins being better understood.

4.1 Structure of Class I Fusion Proteins

Class I fusion proteins typically are homooligomeric glycoproteins with a single transmembrane domain. They are oriented perpendicular to the viral membrane and often form characteristic spikes. At or near the N-terminal end, these proteins contain an amphiphilic region of 15 to 35 amino acids, referred to as *fusion peptide*, which is essential for function. All class I fusion proteins have one remarkable feature in common: before the viruses bud from the host cell, the otherwise stably folded fusion proteins are posttranslationally processed by a single proteolytic cut yielding a stable globular N-terminal and a metastable C-terminal fragment containing the transmembrane domain. The metastable C-terminal fragments are the fusion catalysts. When these proteins are triggered by binding to a surface receptor or by low pH, as encountered after endocytosis of the virus particle, they spontaneously undergo major conformational changes. As a result, elongated helical bundles (usually consisting of trimeric coiled coils) are formed and the previously buried fusion peptides are exposed at the tip of the bundle. After completion of the conformational transition, the resulting protein is very stable and inactive. Thus, viral fusion proteins are ''single-shot'' devices resembling a loaded spring: they can be triggered only once. Biologically, this makes sense since they are needed only once in an infectious fusion reaction.

The fusion peptides play an essential role in virus-mediated fusion. These domains insert into the membrane of the host cell upon activation with the large hydrophobic side chains buried in the interior of the membrane. Perturbation of the amphiphilic nature of the fusion peptide,

for example by site-directed mutagenesis, either cripples or completely inactivates fusion activity. Interestingly, many isolated fusion peptides derived from viral fusion proteins are efficient fusogens: when added to a suspension of liposomes, spontaneous fusion occurs. However, it is likely that their prime role is to provide a firm anchor in the target membrane.

Much of our understanding of viral membrane proteins is derived from the influenza hemagglutinin (HA) fusion protein that for many years served as a paradigm for class I fusion proteins. It is the only fusion protein for which fragments were crystallized both for the metastable prefusion state and the relaxed postfusion state. In the prefusion state, the HA trimer contains a central trimeric coiled coil that is connected to the fusion peptide by a long loop that folds back to the base of the molecule. Triggering of the protein by low pH results in two major rearrangements. First, the connecting loop is converted into a helix that now extends the coiled-coil region, effectively propelling the fusion peptide from the base to the top of the elongated molecule. Second, a reverse turn is generated in the middle of the original helix, rotating the C-terminal part by 180°, with these helical parts and some nonhelical extensions now fitting into the grooves of the central trimer (Fig. 3). While the purpose of the first molecular motion is obvious (exposure of the fusion peptide and its ''shooting'' into the target membrane), the significance of the second motion was only fully appreciated when structures of other viral fusion proteins (e.g. gp41 of the human immunodeficiency virus) were solved in which such back folding (resulting in an inner coiled coil and an outer ring of inverted helices) is more obvious than in HA. It is thought that the second motion repositions the transmembrane domain from the base of the molecule to its tip, that is, adjacent to the fusion peptide. It should be borne in mind, however, that the region adjacent to the transmembrane domain was not part of the structure, and thus the precise position of the transmembrane domain in the relaxed form remains to be determined. In addition to HA, the crystal structures of several additional class I proteins have been determined, but for these only the relaxed structures are available. They all contain a central trimeric coiled coil and three surrounding outer helices although there is no sequence similarity between most of these proteins.

4.2 Fusion Mechanism of Class I Proteins

Despite a wealth of structural information and numerous studies on fusions mediated by wild-type and mutated class I fusion proteins, there is still no consensus about the mechanism by which these proteins fuse membranes. It is undisputed that any interference with the conformational change (or part of it) either inhibits fusion completely or leads to an arrested intermediate state, suggesting that these fusion proteins are nanomachines that exert mechanical force on the membranes destined to fuse. The most popular model (''jackknife model'') envisions fusion as a two-step process progressing via defined intermediates (Fig. 3). In the first step, the fusion peptide is propelled at the tip of the protein, resulting in its insertion and thus anchoring in the host cell membrane. In this state, the fusion protein is in an extended conformation, being connected to the viral membrane by its transmembrane domain and to the host cell membrane by its fusion peptide. In the second step, the

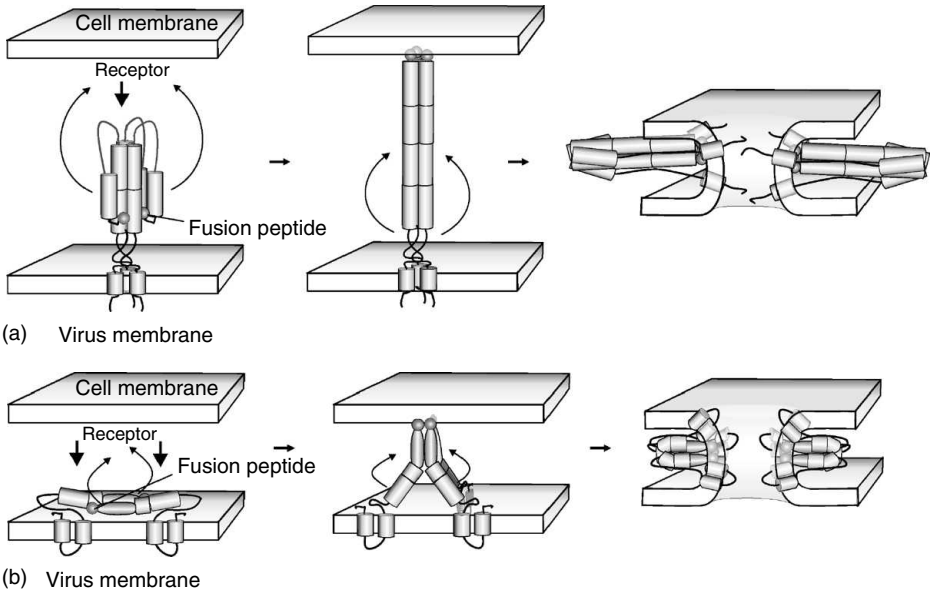

Fig. 3 Models for membrane fusion mediated by class I (a) and class II (b) viral fusion proteins involving a two-step mechanism. In the first step, the fusion peptides are exposed and are inserted in the target membrane. In the second step, the C-terminal part of the proteins undergoes another conformational change, resulting in bending/pulling that results in fusion. Red balls depict the fusion peptides, green cylinders the transmembrane domains. Note that the cellular receptors and the viral receptor–binding proteins are not shown. The colors indicate different domain of the proteins. Note that in class I proteins the colored boxes indicate α-helices, whereas in class II proteins they define folded domains that are not helical. Arrows indicate the presumed movements (see color plate p. xxiii).

outer helices revert and fold back on the rigid coiled coil, thus dragging the transmembrane domains from the base to the top of the molecule adjacent to the fusion peptide. As a result, the two membranes are forced into close apposition, with the fusion peptides probably destabilizing the monolayer surface by displacing water at the contact site, facilitating the formation of nonbilayer transition states.

Although widely accepted, the jackknife model suffers from some shortcomings. First, the rotational symmetry of the trimeric fusion proteins (see cartoon in Fig. 3) precludes bending to one side (as mandatory for the jackknife model) unless one assumes that the second folding step occurs asynchronically, that is, that back folding in only one of the subunits allows for lateral bending of the molecule. Second, it has been known for some time that activation of HA in the absence of a target membrane results in insertion of the fusion peptide into the viral membrane. Again, it is difficult to explain how such ''reverse'' insertion is prevented upon contact with a host membrane. To overcome these problems, alternative mechanisms were proposed that differ from the jackknife model in that the fusion peptide is either exclusively or partially inserted into the viral membrane. According to the first scenario, the formation of the coiled coil

would then exert a strong bending force on the viral membrane, while the protein remains attached to the cell membrane by binding to the receptor. Fusion proteins grouped in a ring around the prospective fusion site would create a membrane protrusion that extends in the direction of the target membrane, resulting in its destabilization and initiation of fusion. A second alternative is that the fusion peptides of a given trimer are inserted randomly into the viral and the target membrane. In this scenario, the extension of the central coiled coil rather than the backfolding would exert the primary pulling force that brings the membranes in close apposition. While both of the latter models account for the ''symmetry problem,'' experimental support for either of them presently is lacking.

4.3 Class II Viral Fusion Proteins

Class II fusion proteins including the E-glycoproteins of flaviviruses and alphaviruses are also activated by low pH to undergo conformational changes, but it appears that the mechanisms are very different from those of class I proteins. Recently, the structure of whole virus particles containing class II fusion proteins has been solved by a combination of cryoelectron microscopy and crystallography. These fusion proteins form an interconnected lattice on the viral surface. They are oriented horizontally rather than perpendicular to the viral membrane. Proteolytic activation usually occurs in an accessory protein rather than in the fusion protein itself. α-helices and coiled coils are not part of the protein structure, rather, they are primarily composed of β-strands. The E-glycoproteins have three domains: an N-terminal domain, a middle domain that carries the fusion peptide (rather than being positioned near the N-terminus), and a C-terminal domain containing the transmembrane domain. The fusion peptides form short loops, which, in the nonactivated form are located close to the viral membrane and are covered either by an accessory protein involved in receptor binding or by a dimerization interface. Upon activation, the fusion peptides are exposed by what appears to be a coordinated conformational change of neighboring molecules. In the case of the Semliki forest virus, activation reorients the E1-fusion protein from a dimer with its accessory protein E2 to a homotrimer, associated with a movement away from the viral membrane surface (Fig. 3). This motion probably causes the insertion of at least part of the fusion peptides into the target membrane, probably in a β-barrel conformation. *In vitro* fusion of viruses carrying class II proteins with artificial membranes is considerably faster than that of viruses with class I proteins.

Despite the differences in structure, recently solved crystal structures of class II fusion proteins have revealed striking similarities between class I and class II fusion proteins. In both cases, activation leads to conformational rearrangements that result in a juxtapositioning of the transmembrane domain with the fusion peptide, with the final conformation being very stable. In the relaxed low pH trimeric form, domains 1 and 2 form a thick, rodlike structure with the fusion peptides at their tips, again reminiscent of the class I protein structure. Thus, it is conceivable that despite a very different structural basis the fusion mechanisms of class I and class II proteins are similar (Fig. 3).

5
Mitochondrial Fusion

Mitochondria continuously undergo dynamic shape changes including frequent fusion and fission events. Since mitochondria are surrounded by an inner and an outer membrane with very different protein compositions, homotypic fusion of mitochondria must involve the consecutive fusion of the outer and inner membrane, respectively.

Until recently, the protein machinery involved in mitochondrial fusion has remained enigmatic although it is clearly distinct from the protein complexes mediating fusions in the secretory pathway. A few years ago, a first putative protein participating in mitochondrial fusion has been discovered. Originally identified as a gene involved in the formation of a special mitochondrial aggregate in the sperm of Drosophila, a conserved integral membrane protein, termed fzo (for ''fuzzy onion''), was discovered to be essential for fusion. Fzo represents a small protein family of evolutionary highly conserved proteins (termed *mitofusins* in mammals) that possess two transmembrane domains and an N-terminal GTPase domain, with both the C- and N-terminus facing the cytoplasm. Adjacent to the membrane-anchor domain are regions that are predicted to have a high propensity for the formation of coiled coils, thus bearing superficial similarities with bona fide fusion proteins such as the class I viral fusion proteins and the SNAREs. While yeast possesses a single family member (Fzo1p), higher organisms and mammals contain two mitofusins.

Recently it has been discovered that mitofusins can form dimers in which the C-terminal regions of mitofusins form antiparallel coiled coils, thus tethering the outer membranes of two adjacent mitochondria. Furthermore, an active GTPase domain is required for mitochondria to fuse. However, it is not clear at present whether the role of mitofusins is confined to tethering or whether they are also involved in later states of the fusion reaction. Additional proteins are likely to be involved including, for example, Ugo1p, an outer membrane protein with several transmembrane domains, and Mgm1p, a dynamin-like GTPase on the outer surface of the inner membrane. Furthermore, recent screens in yeast have uncovered more genes that appear to be involved in mitochondrial fusion and whose molecular roles are yet to be elucidated.

6
Fusion Reactions in the Secretory Pathway

6.1
Overview

The term *secretory pathway* refers to all organelles that originate from the endoplasmic reticulum and that are connected by defined vesicular trafficking routes. They include both the biosynthetic route, leading from the endoplasmic reticulum to the Golgi complex, and from there lead either to the plasma membrane or to endosomal intermediates, and the endocytotic/degradative route leading from the plasma membrane to the lysosomes via early and late endosomal intermediates. Additional connections and shortcuts are provided by further specialized trafficking routes, some of which may be tissue and cell-type specific such as regulated exocytosis (Fig. 4).

Each trafficking step in the secretory pathway can be broken down into three

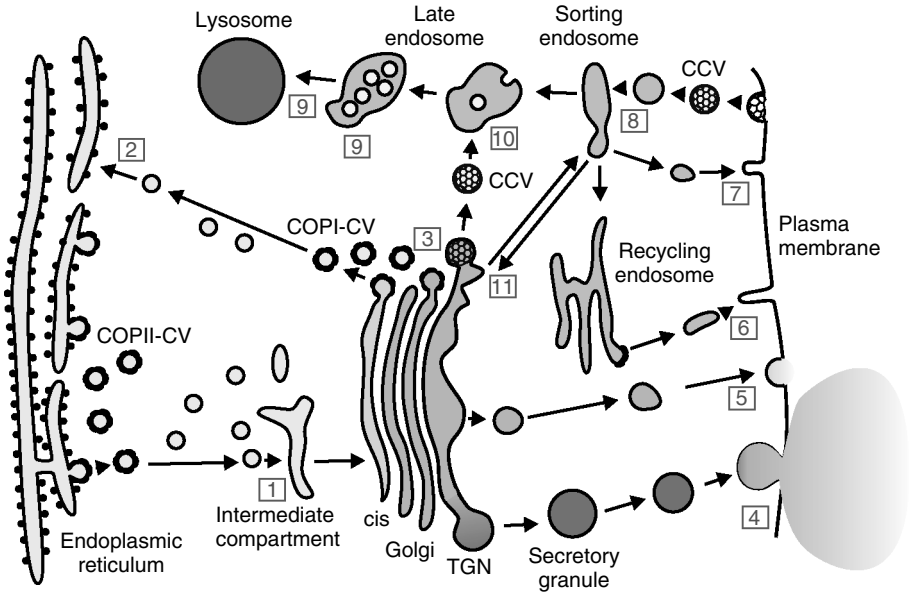

Fig. 4 Overview of the secretory pathway in a prototype eukaryotic cell. The boxed numbers indicate distinct fusion steps. CCV, clathrin-coated vesicle, COPI/II-CV, COPI/II-coated vesicle, TGN, *trans*-Golgi network. The biosynthetic route is depicted in green, the endocytotic pathway in pink (see color plate p. xxv).

elementary steps: the generation of a transport vesicle by budding from a precursor membrane, the movement of the vesicle to its target membrane mediated by the cytoskeletal machinery, and the consumption of the transport vesicle by fusion with its target compartment. In addition, there is ''homotypic'' fusion between organelles of the same class such as endosomes and cisternae of the endoplasmic reticulum. Intracellular trafficking pathways are highly organized, and they exhibit a high (but not absolute) degree of specificity. Thus, a vesicle derived from the endoplasmic reticulum will normally not fuse with the plasma membrane. Furthermore, vesicles originating from common sorting platforms such as the *trans*-Golgi network or the early endosome may have different destinations. This specificity is a feature of the organelles and trafficking vesicles, and as discussed in more detail below it is encoded in specific proteins that provide layers of regulation.

Unlike viral fusion proteins that single handedly carry out the jobs of docking and fusion, complex supramolecular assemblies mediate fusion in the secretory pathway, which act in concert with each other and carry out cascades of sequential reactions. These supramolecular machines are not represented by stable entities with fixed stoichiometries. Rather, they are assembled on demand and dissociate from the fusion site when the task is completed.

Despite the diversity of intracellular fusion reactions with respect to structure and kinetics, it appears that the fusion machines of the secretory pathway operate by principally similar mechanisms. This is suggested by the fact that several of the

proteins required for docking and fusion represent evolutionarily conserved protein families that have diversified to adjust to the specific demands of individual fusion reactions. Such conserved proteins include the small GTPases of the Ypt/Rab family, the SM proteins, and the SNARE proteins.

Before intracellular trafficking organelles fuse, they need to be transported into close proximity. Furthermore, signaling between the membranes is required in order for them to "know" that another potential fusion partner is nearby. This also involves "proofreading," that is, mechanisms that ensure that the fusion partner is appropriate. These steps may or may not be associated with the establishment of physical contact that proceeds via first loose ("tethering") and then firm ("docking") contact. Next, the fusion reaction is executed which may require prior activation of the fusion machinery. After fusion, the fusion machinery is disassembled and regenerated to be available for another round of fusion.

Intriguingly, it appears that with exception of the presumed fusion catalysts (the SNARE proteins) and some regulatory proteins involved in specialized fusion reactions (such as the synaptotagmins), all other proteins are recruited on demand from the cytoplasm and thus are not permanently associated with the membrane. The advantage of such a mechanism is probably to minimize the "efforts" a cell needs to spend on protein recycling. After fusion of a trafficking vesicle, membrane-resident fusion proteins need to be returned by membrane trafficking to the precursor compartment for the proteins to be reused. This necessity also explains why membrane-bound fusion proteins (SNAREs) are not only present in the organelle for whose fusion they are responsible but also in all other organelles belonging to the recycling pathway required for returning these proteins to their original compartment.

6.2 Tethering and Docking – the Role of Rab Proteins and Their Effectors

What is the first step in the reaction cascade leading to fusion of two proximal organelles? Very little is known about the initial signaling events. However, it is well established that Rab GTPases play a central role in defining a site for fusion and in orchestrating the recruitment of protein complexes.

Rab proteins belong to the ras-superfamily of small monomeric GTPases. They operate as molecular switches that exist in an active GTP-bound and an inactive GDP-bound conformation. The switch between these conformations is made by regulatory proteins, the GTPase-activating proteins (GAPs) that stimulate the intrinsic GTPase activity of the rabs, and the guanine nucleotide exchange factors (GEFs) that replace GDP with GTP. Superimposed on the GTP-GDP cycle is a membrane association–dissociation cycle. Rab proteins carry posttranslationally attached polyprenyl chains that anchor the proteins in the membrane. GDP-Rab proteins are removed from the membrane by the action of a universal protein termed GDP-dissociation inhibitor (GDI) that forms soluble complexes with all GDP-Rabs by hiding the prenyl anchor in a hydrophobic pocket. Rebinding is associated with GTP-reloading by GEFs and may require assistance of additional proteins such as the members of the Yip/Pra1 family. These proteins displace GDI and thus are termed GDFs (for GDI displacement factors).

Rab proteins display the most organelle-specific localization of all known trafficking proteins, and they have therefore been assigned a major role in defining the identity of organelles. More than 60 Rab proteins are known in mammalian species. Individual organelles may contain multiple Rabs that probably define functionally distinct subdomains on the organellar surface. However, it is still not understood by which mechanisms this exquisite specificity is achieved.

The main job of active Rab proteins is to recruit specific proteins (termed Rab effectors) to defined sites at the membrane. While many effectors are exquisitely specific for a given Rab protein, others are shared between multiple rabs. Examples for the latter are rabaptin, the TRAPP complex, and mss4. The number of known Rab effectors is increasing steadily, with individual Rab proteins known to bind to dozens of different proteins. Presently, there are no common denominators between the many prospective Rab effectors. However, in some well worked out cases such as the homotypic fusion of early endosomes it is becoming clear that Rab effectors orchestrate the initial steps in docking and fusion. Effectors of the early endosomal Rab5 include large proteins such as EEA1, which is capable of forming homooligomeric structures, tethering prospective fusion partners. Other effectors include a phosphatidylinositol 3-kinase and proteins containing FYVE and PX domains that in turn bind to specific polyphosphoinositides. Phosphoinositides are known to be centrally involved in intracellular membrane traffic, and it is possible that together with an active Rab they provide a local binding site for further proteins that is highly specific for a given fusion step. For instance, EEA1 is both an effector for Rab5 and it contains a FYVE domain that binds to phosphatidylinositol-3-phosphate, suggesting that only the combination of both – active Rab5 and a sufficiently high concentration of phosphatidylinositol-3-phosphate – is effective in recruiting EEA1 to the membrane.

While it is generally agreed upon that active Rabs recruit docking and tethering complexes, the underlying molecular mechanisms are not known. Many Rab effectors are multiprotein complexes including the exocyst (presumably involved in constitutive exocytosis), the GARP, TRAPPI, TRAPPII, and COG complexes that are involved in trafficking steps at the Golgi apparatus, and the HOPS/VpsC-complex that functions in the homotypic fusion of yeast vacuoles. For the homotypic fusion of yeast vacuoles, sequentially occurring assembly and disassembly reactions were worked out involving components of the VpsC-complex and additional proteins such as LMA1. An example from the other end of the spectrum is represented by the RIM proteins, effectors of the Rab3 that function in neurotransmitter release at the synapse. RIM is part of the so-called active zone, an electron-dense structure at the presynaptic plasma membrane to which synaptic vesicles dock. Active zones consist of an insoluble supramolecular complex containing a set of large and insoluble proteins including Piccolo/aczonin, bassoon, ERCs (acronym for ELKS/Rab3-interacting molecule/CAST), RIM-binding proteins 1 and 2, and α-liprins. Taken together, there is little similarity between the components of these multiprotein complexes, and it is thus conceivable that the diversity of Rab effectors is responsible for imprinting specific features to each fusion reaction in the secretory pathway and to specialized fusions in certain cell types.

6.3 Fusion – SNARE Proteins as Fusion Catalysts

SNARE proteins (acronym for soluble NSF acceptor protein receptors) represent a superfamily of small and mostly membrane-bound proteins that are conserved throughout the eukaryotic kingdom, with 24 members in yeast, at least 35 members in mammals, and more than 50 in plants. SNARE proteins typically contain a C-terminal transmembrane domain, an adjacent stretch of 60–70 amino acids arranged in heptad repeats that is characteristic for the entire SNARE superfamily and that is referred to as *SNARE motif*, and an N-terminal region that either consists of only few amino acids or else, is composed of a separately folded domain (Fig. 5). There is considerable heterogeneity among SNARE family members both with respect to primary structure and to domain structure. In addition to the prototypical SNARE described above, some family members contain two instead of one SNARE motifs. Examples include the neuronal SNARE SNAP-25, its relatives SNAP-29 and SNAP-23, and the yeast SNAREs Sec9p and Spo20. In these proteins, the SNARE motifs are connected with a linker region. These SNAREs lack a transmembrane domain; instead, some of them carry hydrophobic palmitoyl side chains. Other exceptions include SNAREs with single SNARE motifs that carry either a posttranslationally added polyprenyl anchor (such as Ykt6) and the yeast SNARE Vam7 that lacks a membrane anchor altogether.

The importance of SNARE proteins was originally recognized because of three independent lines of evidence: first, the SNAREs involved in neuronal exocytosis (including the proteins synaptobrevin/VAMP, SNAP-25, and syntaxin 1) were identified as the targets of botulinum and tetanus toxins, second, the proteins were recognized in genetic screens in yeast as being essential for intracellular fusion reactions, and third, the SNAREs were identified as the membrane receptor

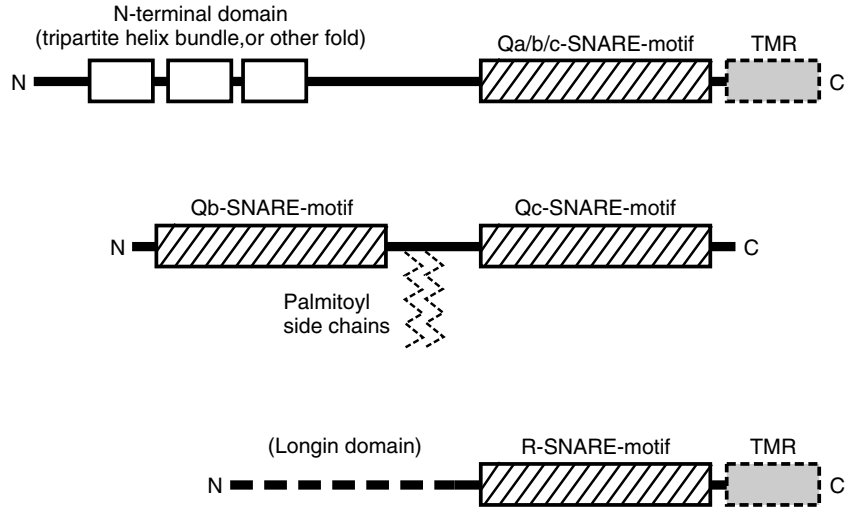

Fig. 5 Domain structures of SNARE proteins. Dotted lines delineate domains that may be absent in some of the family members. TMR, transmembrane region.

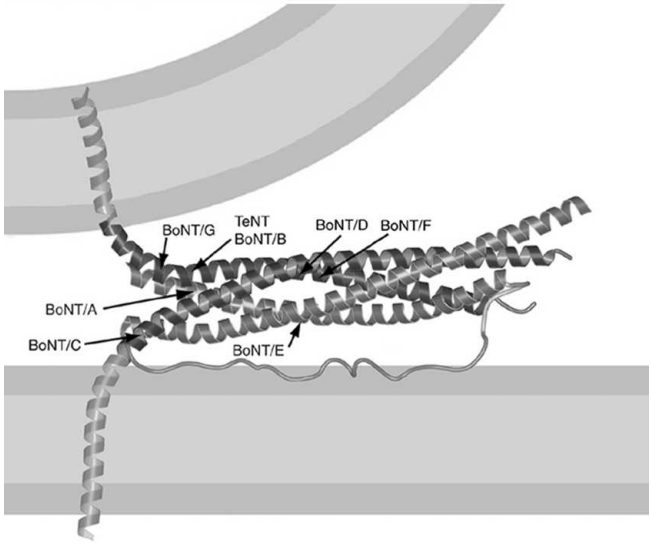
of the ATPase NSF (hence the name SNARE) that was previously recognized as an important component of intracellular fusion reactions.

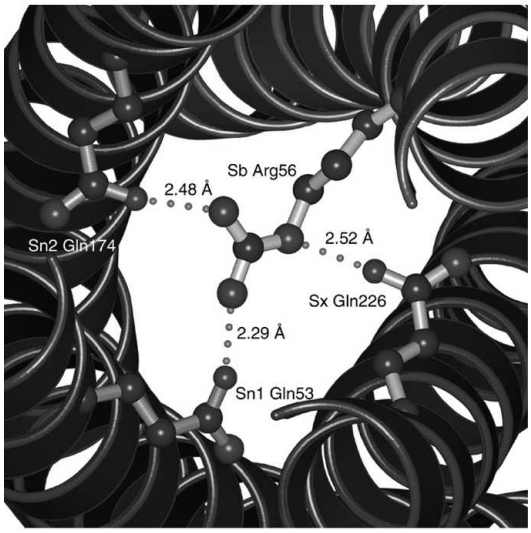
6.3.1 The SNARE Assembly–Disassembly Cycle

SNARE proteins undergo an assembly–disassembly cycle that involves the SNARE motifs and that is essential for membrane fusion. Monomeric SNARE motifs are unstructured in solution. However, when appropriate sets of SNAREs are combined, they spontaneously form complexes in which four different SNARE motifs form a stable helical bundle. The crystal structures of two only distantly related SNARE complexes revealed an extraordinary degree of structural conservation despite limited sequence homology. The structures are represented by four elongated α-helices that form a coiled coil containing 16 layers of interacting amino acid side chains stacked on top of each other. These amino acids are mostly hydrophobic with the exception of an unusual layer in the middle of the complex, termed ''0'' layer, to which three SNARE motifs each contribute a glutamine, and one an arginine (Fig. 6). On the basis of this highly conserved layer, SNAREs are now classified into subfamilies termed



(a)

Fig. 6 (a) Crystal structure of the neuronal SNARE complex containing syntaxin 1 (red), SNAP-25 (green), and synaptobrevin/VAMP (blue). The structure is modeled between two membranes, the transmembrane domains and immediately adjacent residues are not part of the structure. (a) Structure of the ionic ''0'' layer that is conserved among all SNAREs and that is the basis for the classification of SNAREs into Q- and R-SNAREs, respectively. Modified from Sutton, B., Fasshauer, D., Jahn, R., Brünger, A.T. (1998) Crystal structure of a core synaptic fusion complex at 2.4 Å resolution, *Nature* **395**, 347–353 (see color plate p. xxviii).



(b)

Fig. 6 (*Continued*)

Q-SNAREs and R-SNAREs, with the Q-SNAREs being further subdivided into Qa-SNAREs (representing the ''true'' syntaxins), Qb-SNAREs, Qc-SNAREs (homologs of the two SNARE motifs of SNAP-25, respectively), and R-SNAREs (relatives of VAMP/synaptobrevin). The division of SNAREs into these four subfamilies is strongly supported by additional similarities that were derived from sequence comparisons. As a general rule, SNARE complexes can only form if one SNARE motif of each subfamily is contributed. It replaces the previous classification of SNAREs to v-SNAREs (vesicular SNAREs) and t-SNAREs (SNAREs residing in target membranes) since the intracellular topology that was used for this classification does not agree with the subclasses as defined by activity, crystal structures, and sequence alignment. In fact, *in vitro* SNARE motifs of the appropriate subclasses can – within certain limits – substitute for each other.

Although due to an unusual hysteresis, it is not possible to determine the free energy of SNARE assembly, assembly proceeds downhill an energy gradient. The stability of assembled SNARE complexes is remarkable, requiring temperatures above 80 °C or very strong denaturants such as 5 M guanidinium chloride for dissociation. Both the elongated structure of the helical bundle and the stability toward heat, denaturants, and proteases is strikingly parallel to the relaxed conformation of class I viral fusion proteins discussed above. However, unlike the viral fusion proteins, SNAREs are reactivated by disassembly, involving the ATPase NSF (acronym for NEM-sensitive factor). On its own, however, NSF cannot interact with SNAREs; it requires cofactors termed SNAPs (acronym for soluble NSF attachment proteins). Both in yeast and in mammals only one NSF gene has been found. In contrast, mammalian species contain three variants of SNAP termed α-, β-, and γ-SNAP respectively,

with α-SNAP being the ubiquitous isoform. Three SNAPs bind to one SNARE complex, resulting in the recruitment of NSF. Remarkably, the SNAP-NSF system interacts with all known SNARE complexes in this manner despite the fact that the surface amino acid composition is highly variable with respect to charge and size. The crystal structure of the yeast SNAP-homolog Sec17p revealed a rigidly packed protein with an N-terminal region in which nine α-helices are packed against each other in an antiparallel fashion, resulting in a bent sheet and a C-terminal globular region. The N-terminal region is responsible for SNARE binding, whereas the C-terminal region recruits NSF. Several SNAP mutants are known, which are defective in binding and/or activation of NSF, they are strong inhibitors of all fusion reactions of the secretory pathway.

NSF is a hexameric ATPase that belongs to the AAA superfamily (ATPases associated with other activities). AAAs frequently operate as unfoldases, that is, they dissociate tightly packed or aggregated proteins. NSF monomers consist of three domains: an N-terminal region that binds to the substrate and that undergoes large conformational changes upon ATP hydrolysis, and two homologous ATP binding regions termed D1 and D2, with only D1 being catalytically active and D2 being responsible for hexamer formation. Single-particle and cryoelectron microscopy as well as crystallographic studies on NSF domains and on VCP (valosin-containing protein), a relative of NSF, have revealed that the protein is represented by a double barrel structure with a conspicuous hole in the middle. Presently it is unknown how AAAs manage to disentangle proteins as tightly packed and stable as SNARE complexes. It has been proposed that unfolding involves threading of the substrate through the central channel (resembling some chaperones). Alternatively, it is possible that the barrel opens sideways (''clamp loader'') thus getting a ''grip'' on the substrate and exposing it to hydrophobic side chains in the interior of the oligomeric molecule. The ATP-requirement has not yet been precisely determined, and thus it is not known whether a full catalytic cycle of all six subunits is required for disassembly. Mutations of NSF are known both in yeast and in Drosophila, which loose activity at mildly elevated temperature, resulting in a general impairment of membrane traffic. In Drosophila, the dominant effect is in synapses where exocytotic release of neurotransmitters is affected first, resulting in paralysis (''comatose'') and an accumulation of SNARE complexes.

6.3.2 Mechanism of SNARE-mediated Membrane Fusion

The most widely accepted model describing how SNAREs mediate membrane fusion implies that it is the spontaneous assembly of SNAREs into SNARE complexes that drives the membrane merger. According to this model, each of the membranes destined to fuse contains complementary sets of SNAREs that upon close contact spontaneously interact with each other in ''trans'' and form a SNARE complex by zippering up from the N- toward the C-terminal ends of the respective SNARE motifs. Such zippering would force the transmembrane domains in close apposition. The energy being released during assembly is used to overcome the repulsive energy barrier separating the membranes, thus exerting strain on the membranes. During fusion, the SNAREs change from a strained ''trans'' into a relaxed ''cis'' conformation, in a remarkable parallelism to the class I viral fusion proteins. After fusion is complete, the NSF-SNAP

disassembly system then dissociates the complex and makes available the SNAREs for another round of fusion.

This model, although not undisputed, is supported by a large body of evidence such as

- experiments using yeast vacuolar fusion *in vitro* have shown that NSF is not required for the fusion reaction but rather is needed for a preceding activation step;
- many SNARE mutants from yeast, flies, and worms causing functional impairments map to amino acids of the central interacting layers, supporting the view that the formation of the helical bundle is critical for fusion;
- cells can be enticed to fuse when SNAREs are ''flipped,'' that is, expressed by facing the exterior rather than the cytoplasm;
- any interference with SNAREs in intact cells or in cell-free assays using antibodies, clostridial neurotoxins, or recombinant SNARE motifs as competitors invariably inhibits fusion;
- proteoliposomes reconstituted with appropriate sets of SNAREs spontaneously fuse with each other, and this fusion requires the formation of SNARE complexes.

6.3.3 Conformational Intermediates of SNAREs

Recent studies have shown that the zippering model described above, while providing a useful overall description of the SNARE mechanism, is an oversimplification that needs to be refined. For instance, while SNAREs spontaneously form complexes and fuse liposomes *in vitro*, these reactions are many orders of magnitude slower than their biological counterparts, although high protein concentrations were used in the assays, and artificial docking of the liposomes also does not accelerate the reaction. Similar to viral fusion proteins, the attention has therefore focused on conformational intermediates of the SNARE cycle.

A model outlining potential intermediate steps is shown in Fig. 7. This model is primarily based on studies of the SNARE proteins involved in neuronal exocytosis that served as paradigms. It is possible that certain depicted states do not exist in other SNARE complexes. The following features are noteworthy:

- *Hotspots of concentrated clusters of SNAREs.* In plasma membranes, SNAREs are not uniformly distributed across the membrane but rather concentrated in microdomains. These microdomains are dependent on the presence of cholesterol in the membrane but are not resistant to detergent, that is, they are different from rafts. The local concentration of SNAREs in these hotspots appears to be very high. This is particularly noteworthy in neurons where the two Q-SNAREs syntaxin 1 and SNAP-25 each contribute at least 1% of total brain protein, making them by far the most abundant membrane proteins in the nervous system. In PC12 cells, secretory granules exclusively undergo exocytosis on such hotspots suggesting that for fusion to be efficient many SNARE complexes need to cooperate. In addition, the SNAREs in these hotspots readily form complexes with both exogenous and endogenous SNAREs suggesting that activation of SNAREs prior to fusion is not rate limiting.
- *SNARE acceptor complexes.* Considering that the SNARE motifs are unstructured in solution, it is not surprising that SNARE complex formation *in vitro*

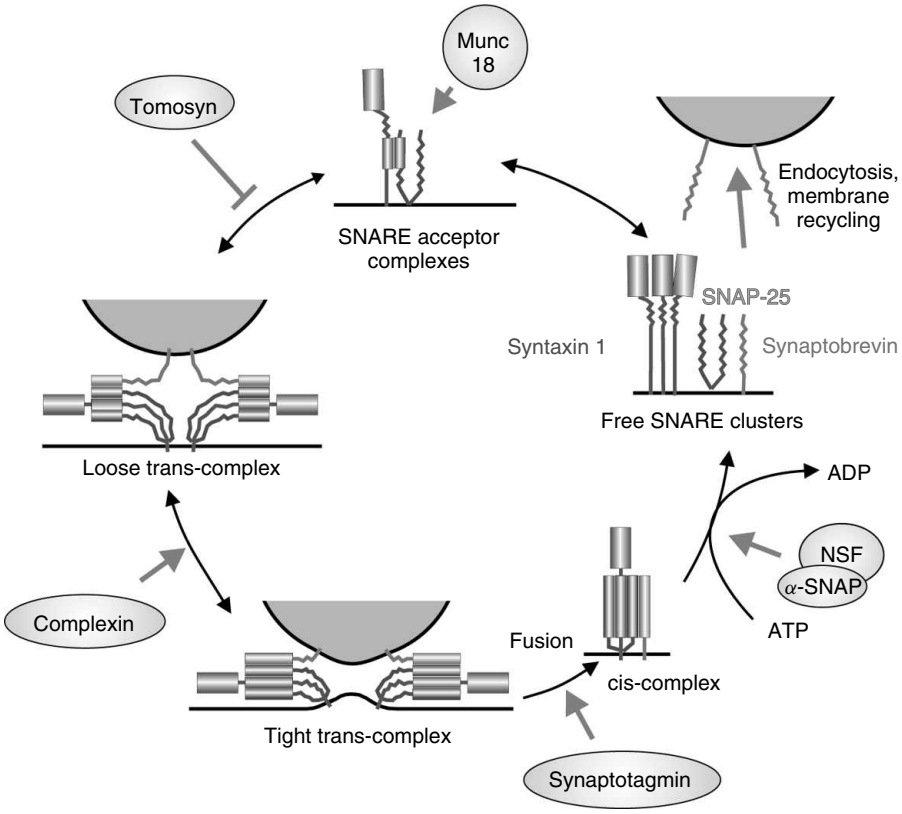


Fig. 7 Model of the cycle of the neuronal SNAREs and its regulation by accessory proteins. See text for details.

is exceedingly slow as it requires the simultaneous association of four different molecules. *In vitro*, the neuronal Q-SNAREs syntaxin 1 and SNAP-25 form a binary complex consisting of two syntaxin and one SNAP-25 molecule. This complex resembles the SNARE core complex but is less stable. For synaptobrevin to bind, one of the syntaxins needs to be displaced which appears to be rate limiting. Recent work revealed that an unstable intermediate is formed between SNAP-25 and a single syntaxin molecule. Binding of synaptobrevin to this complex appears to be considerably faster. This intermediate may represent the ''true'' acceptor complex that can either recruit a second syntaxin, resulting in a nonconstructive ''dead-end'' reaction, or bind synaptobrevin in a pathway leading to fusion. Intriguingly, independent lines of evidence suggest that such acceptor complexes are stabilized by SM proteins (see below).

- *SNARE trans-complexes*. Regulated exocytosis implies that the pathway leading to fusion is arrested at some step, requiring activation by a trigger that is usually an elevation of intracellular Ca^{2+}. In neuronal exocytosis, the delay time between Ca^{2+} triggering and membrane fusion is extremely short (<1 ms). The

question arises whether SNARE assembly can be arrested at an intermediate state, with the N-terminal parts of the SNARE motifs being already assembled, whereas the C-terminal parts are still apart. Evidence for such intermediates primarily stems from studies of exocytosis of chromaffin cells, which can be monitored with high time resolution using electrophysiological techniques. Following a jump in intracellular Ca^{2+}, distinct pools of granules are observed that undergo exocytosis with a characteristic time constant: a cytoplasmic depot pool, a reserve pool representing membrane-attached vesicles that still need to be activated (''primed''), and two pools of release-ready vesicles, referred to as slowly releasable pool (SRP) and rapidly releasable pool (RRP). These pools are in dynamic equilibria with each other. Recent studies suggested that in the RRP, SNAREs are associated with each other in a trans-complex prior to fusion, and similar conclusions have also been reached from studies at the crayfish neuromuscular junction. While all these studies are indirect (i.e. conclusions about molecular states are drawn from kinetic data), they suggest that metastable folding intermediates may exist in the SNARE assembly pathway, again paralleling similar observations on class I viral fusion proteins.

- *Contribution of SNARE transmembrane domains.* For the final step in membrane fusion, the model predicts that a pulling force is exerted on the membranes, suggesting that the linkers between the transmembrane domains and the SNARE motifs are stiff. Both theoretical calculations and experimental evidence suggest that this may be the case. Furthermore, it is possible that the transmembrane domains do more than just providing a membrane anchor. For instance, peptides corresponding to SNARE transmembrane domains have recently been shown to be capable of fusing liposomes, suggesting that they may also be involved in destabilizing the bilayer. Furthermore, recent studies indicate that the transmembrane domains of syntaxin may contribute to the fusion pore structure. Also, transmembrane domains of syntaxin and synaptobrevin have the capacity to form homooligomers and heterooligomers, again supporting the view that in addition to providing membrane attachment they may participate in transition states in a specific manner.

6.3.4 Topology and Specificity of SNAREs in Intracellular Fusion Reactions

The model outlined above for SNARE function implies that of the fusing membranes each one carries at least one of a complementary set of SNAREs that contains a transmembrane domain. In neuronal exocytosis this requirement is fulfilled, with synaptobrevin (R-SNARE) being localized primarily to the synaptic vesicle and syntaxin 1 (Qa-SNARE) to the plasma membrane. Intracellular fusion reactions, however, often involve SNARE complexes in which three or all four SNARE motifs are contributed by SNAREs possessing a transmembrane domain, allowing, at least in theory, variable distributions between the membranes. However, it is conceivable that the need for preformation of acceptor complexes limits the choices, for example, if, as in the case of neuronal exocytosis, an acceptor complex consists of Qa/Qb/Qc-SNARE motifs. Indeed, liposome fusion experiments suggested that only one type of topology of a given SNARE complex results in fusion. However, in yeast there are examples of SNAREs that

may function in different complexes with different topology. For instance, the yeast R-SNARE Sec22p functions both in anterograde as well as in retrograde traffic between the endoplasmic reticulum and the Golgi apparatus. In anterograde traffic, Sec22p appears to be colocalized with the Qb- and Qc-SNAREs Bos1p and Bet1p respectively, on the transport vesicle, with the Qa-SNARE Sed5p residing in the acceptor membrane. In contrast, all three Q-SNAREs for retrograde traffic including Qa (Ufe1p), Qb (Sec20p), and Qc (Use1p) are localized to the endoplasmic reticulum, with Sec22p being the sole functional SNARE on the retrograde transport vesicle.

The example of yeast anterograde and retrograde traffic between the endoplasmic reticulum and the Golgi apparatus also raises the question to which extent SNARE pairing is specific. Although this issue continues to be controversially discussed, the following points can be made:

- *In vitro*, SNAREs can be assembled into SNARE complexes rather promiscuously as long as the QabcR-SNARE rule for SNARE complexes is obeyed. However, while in some experiments no differences were observed between different R- or Q-SNAREs, respectively, it is likely that promiscuity is not absolute, that is, that not every SNARE of a given subfamily is capable of substituting for a particular family member in a given complex.
- Certain SNAREs are known to be involved in different trafficking steps involving different SNARE partners. In addition to Sec22p discussed above, other yeast examples include Sed5p (a Qa-SNARE operating in ER to Golgi, and intra Golgi trafficking steps), Vti1p (a Qb-SNARE operating in traffic to the *cis*-Golgi, and from the Golgi to the prevacuole (late endosome) and the vacuole compartment), and Ykt6p (an R-SNARE operating in retrograde traffic to the Golgic, in traffic from the Golgi to the prevacuole (late endosome) and the vacuole compartment, and in anterograde traffic from the ER to the Golgi).
- Conversely, in a given SNARE complex certain SNAREs can functionally substitute for each other, albeit the efficiency appears to be lower than with the ''cognate'' SNARE. For instance, in yeast Ykt6p can substitute for Sec22p in anterograde but not retrograde ER to Golgi traffic, and SNAP-23 can substitute for SNAP-25 in exocytosis of chromaffin granules. Such functional substitutions of one SNARE for another one may explain why genetic deletion of individual SNAREs in some cases is known to yield surprisingly mild phenotypes.

The question then arises to which extent SNARE complexes are specific for a given fusion step. Although a definitive answer cannot be given at this time, it appears that the SNAREs active in a specific intracellular fusion event are precisely regulated, that is, a given SNARE complex functions only in one defined step even if some flexibility is allowed in the identity of some of its participating SNARE proteins. It should be noted, however, that presently it cannot be excluded that more than one SNARE complex operates in parallel in certain fusion events.

It is not known how nonspecific pairing (as observed *in vitro*) is prevented. Furthermore, it is not known by which mechanism the correct SNAREs are selected for a given fusion step. As integral membrane proteins, SNAREs need to recycle by membrane traffic to their resident

membrane after fusion, explaining the widespread intracellular distribution of many SNAREs. Probably every trafficking vesicle carries ''passenger'' SNAREs in addition to the ones needed for the forthcoming fusion step. For instance, in neurons and neuroendocrine cells the recycling pathway of synaptic vesicles includes at least two fusion steps – exocytosis and fusion with an early endosomal intermediate that is reached after endocytosis via clathrin-coated vesicles (CCV). The SNAREs involved in these two fusion steps are distinct (exocytosis: syntaxin 1 (Qa), SNAP-25 (Qbc), synaptobrevin (Qc); endosome fusion: syntaxin 13 or 16 (Qa), Vti1a (Qb), syntaxin 6 (Qc), and VAMP4 (R)). Functionally, there appears to be no cross talk at least between the R-SNAREs as only exocytosis but not endosome fusion is inhibited by clostridial neurotoxins cleaving the R-SNARE synaptobrevin.

6.4 Regulators of SNAREs

An almost overwhelming panoply of proteins is reported to interact with SNAREs in a functionally relevant manner, either regulating fusion or else, being regulated by the SNAREs. In particular, the neuronal SNARE proteins were the target of intense investigations, with syntaxin 1 alone being thought to bind to more than 40 different proteins including many ion channels and receptors. However, in most of these cases the evidence is limited to qualitative binding studies, complemented with perturbation studies in intact cells, making it difficult to assess the specificity of the reported interactions. As discussed above, SNAREs can assume different conformations, and for proteins thought to specifically interact with SNAREs it is essential to determine where exactly these proteins act in the conformational cycle of SNAREs. While the discussion will be restricted here to those proteins for which experimentally supported molecular models are available, it needs to be borne in mind that this is an actively ongoing field of research, with additional proteins likely to be involved.

6.4.1 SM Proteins

SM proteins comprise a small group of conserved cytoplasmic proteins that, as far known, are as essential as SNAREs for all fusion steps of the secretory pathway. In fact, impairment or knock out of SM proteins leads to dramatic phenotypes. For instance, genetic deletion of Munc-18, the SM protein involved in neuronal exocytosis, leads to mice whose nervous system by and large develops normally but in which synapses are completely silent, that is, no exocytotic release of neurotransmitter occurs. There are fewer SM proteins than SNAREs, with four members in yeast and seven in mammals. Crystallographic studies on several SM proteins revealed a high degree of structural conservation, being represented by globular, arch-shaped molecules with a conspicuous cleft.

Numerous genetic and biochemical studies suggest that SM proteins regulate SNAREs. However, major confusion has arisen from the fact that despite a high degree of structural conservation among both SNAREs and SM proteins, the interaction between these proteins, at least *in vitro*, occurs by different mechanisms:

- Munc-18, the SM protein involved in neuronal exocytosis binds to the N-terminal region of the Qa-SNARE syntaxin 1 with high affinity. Like many other SNAREs, syntaxin 1 possesses an antiparallel three-helix bundle at its N-terminus that is connected to the

SNARE motif by a linker region. In a reversible intramolecular transition between an "open" and a "closed" conformation, this N-terminal domain can fold back onto the SNARE motif, preventing the latter from entering SNARE complexes. *In vitro*, Munc-18 exclusively binds to the closed conformation, effectively preventing it from interacting with its SNARE partners. Indeed, the crystal structure of the Munc-18/syntaxin complex reveals that both the N-terminal helix bundle and part of the SNARE motif are bound to the large cleft in the middle of Munc-18, with numerous crystal contacts between Munc-18 and both regions of syntaxin.

- The yeast SM proteins Sly1p and Vps45 (and probably also their mammalian counterparts) bind to the respective Qa-SNAREs Sed5p and Tlg2p in a completely different manner. Here, a short sequence at the N-terminal end of the Qa-SNAREs (i.e. beyond the folded part) binds to the outside of the SM protein. This interaction does not prevent formation of SNARE complexes; rather, it appears to facilitate them.
- In trafficking steps of the endocytotic pathway, the SM proteins do not appear to interact directly with SNAREs. Rather they form complexes with other proteins. Interestingly, this includes not only the SM protein Vps33p that is part of the VpsC or HOPS complex involved in the fusion of vacuoles but also Vps45p that forms a complex with Vac8p. Thus, one and the same SM protein may either bind directly to a SNARE, or else, operate via multiprotein complexes without displaying direct SNARE binding.

Recent evidence suggests that, at least in the case of Sly1p, direct binding to the SNARE is not required for function. Thus, at least some of the bindings described above may be recruiting mechanisms to ensure a sufficiently high concentration of SM proteins at the site of action rather than reflecting part of the mechanism these proteins are involved in, explaining the surprising structural diversity of the SM-SNARE complexes. How then are SM proteins regulating SNAREs? Several lines of evidence suggest that some SM proteins facilitate SNARE assembly, raising the possibility that the main job of SM proteins is to form and maintain SNARE acceptor complexes. Such acceptor complexes are probably unstable and thus hard to measure – the more stable they are, the less energy is left for the ensuing fusion reaction. Furthermore, it has recently been suggested that SM proteins may be part of a proofreading system that ensures pairing of appropriate SNAREs.

6.4.2 Synaptotagmin and Complexin – Regulators of Ca^{2+}-dependent Exocytosis

Exocytosis of synaptic vesicles represents a membrane fusion event that is tightly regulated by the intracellular Ca^{2+} concentration. Delay times between increases in intracellular Ca^{2+} and fusion are extremely short (below 1 ms), suggesting that the system is arrested at a very late step in the pathway of protein–protein interactions leading to fusion. The Ca^{2+} receptor responsible for triggering exocytosis was identified as synaptotagmin, an integral membrane protein of synaptic vesicles. Genetic deletion of synaptotagmin 1 leads to a massive loss of Ca^{2+}-stimulated exocytosis, whereas spontaneous transmitter release persists. Intriguingly, stimulation of exocytosis by means of bypassing the Ca^{2+} trigger (e.g. using the active ingredient of black widow spider venom) persisted but was sensitive to clostridial neurotoxins, documenting that SNARE function

in fusion was not affected in the deletion mutant.

Synaptotagmin is represented by a protein family of hitherto 15 members in mammals. Synaptotagmin 1 and 2 that function in neuronal exocytosis are type I transmembrane glycoproteins, that is, with the C-terminus facing the cytoplasm and the glycosylated N-terminus being exposed to the vesicle lumen. Characteristic for synaptotagmins are two tandem C2-domains (C2A and C2B) that represent Ca^{2+} binding modules binding 3 and 2 Ca^{2+} ions, respectively. Whereas the intrinsic Ca^{2+} affinity of both C2-domains is very low (close to 1 mM), it is increased by almost three orders of magnitude in the presence of acidic phospholipids. Structural studies revealed that the C2-domains provide only a partial coordinations sphere for Ca^{2+} ions that requires acidic phospholipids for completion. C2-domains are present in many additional proteins, and in some instances (e.g. protein kinase C) they are known to convey Ca^{2+}-dependent translocation of the protein to the membrane. Furthermore, Ca^{2+} binding is very rapid and it is not associated with a conformational change in the C2-domain.

While it is undisputed that Ca^{2+} binding to the C2-domains of synaptotagmin triggers exocytosis, the mechanism by which this occurs is still not clear. One possibility is that Ca^{2+}-dependent binding to phospholipids at a site where SNAREs are already forming trans-complexes suffices to further destabilize the membrane surface, leading to the formation of a fusion pore. Indeed, both mutant analysis and ion dependence suggest that phospholipid binding is critical for synaptotagmin function. On the other hand, both Ca^{2+}-dependent and Ca^{2+}-independent binding of synaptotagmin to SNAREs has been observed, raising the possibility that synaptotagmin directly acts upon the SNAREs, for example, by driving the assembly of a partially zippered trans-complex to completion. Intriguingly, Sr^{2+} ions, known to substitute for Ca^{2+} in stimulating exocytosis, promote only phospholipid but not SNARE binding of synaptotagmin. While this finding shows that Ca^{2+}-dependent phospholipid interaction is essential for function, it is conceivable that binding to SNAREs increases efficiency, for example, by positioning the C2-domains precisely before the arrival of the Ca^{2+} signal.

Intriguingly, a phenotype similar to synaptotagmin deletion albeit weaker was observed upon the deletion of complexins, two small and highly homologous isoforms that bind to the surface of assembled neuronal SNARE complexes. Structural studies revealed that part of the complexin forms a helix positioned in the groove formed by syntaxin I and synaptobrevin, which bends away from the SNARE complex toward the C-terminal transmembrane domains. Thus, it is possible that complexins bind and stabilize trans-SNARE complexes, maintaining them in a metastable state and allowing for synaptotagmin to act efficiently in promoting the reaction. Lack of complexins may thus result in less stable SNARE complexes (i.e. complexes that reversibly loosen and tighten), requiring more Ca^{2+} binding to synaptotagmin for efficient fusion.

It remains to be established whether similar regulatory mechanisms also apply to other SNARE-mediated fusion reactions. Many intracellular fusion reactions are known to require Ca^{2+} albeit at a concentration well below 1 μM, that is, the normal cytoplasmic concentration suffices for fusion to proceed. It is conceivable that other ubiquitously expressed synaptotagmin isoforms participate in

such intracellular fusion reactions. However, some synaptotagmins do not bind Ca^{2+} at all, raising the possibility that synaptotagmins may have other functions. Conversely, several additional synaptic proteins possess tandem C2-domains including the active zone components RIM (an effector of Rab3) and Piccolo/Aczonin.

6.4.3 "Pseudo" SNAREs

Two soluble proteins, termed *tomosyn* and *amisyn* respectively are known, which possess C-terminal R-SNARE motifs but otherwise have no similarities to SNAREs. Tomosyn is a large protein of approximately 110 kDa (SNAREs rarely exceed 35 kDa) whose large N-terminal region bears similarity to the lethal giant larvae proteins, whereas amisyn is represented by a smaller protein. Both proteins, when introduced into secretory cells, inhibit exocytosis. Detailed studies on the R-SNARE motif of tomosyn revealed that it directly competes with synaptobrevin in the formation of SNARE complexes, thus reducing the number of active acceptor complexes that are available for fusion. Presently, it cannot be decided whether competition by soluble SNARE motifs (resulting in the formation of nonconstructive cis-complexes) is a general physiological means to downregulate SNARE complexes or whether these proteins are specialized for neuronal exocytosis.

7 Conclusion and Outlook

Despite the diversity of fusion proteins, the examples discussed above show that there appear to be some common denominators between viral fusion proteins and SNAREs. In both cases, fusion is associated with a spontaneous conformational change that involves movement of membrane-anchor domains (transmembrane domains or fusion peptides) over large distances. At the end of the conformational change, an elongated and stiff rodlike structure is generated in which all membrane-anchor domains are localized at one end. Furthermore, both viral fusion proteins and SNAREs are oligomers that exhibit at least some rotational symmetry (trimers in the case of viral fusion proteins, trimers and tetramers in the case of SNAREs). These intriguing features suggest that the basic mechanism of operation is principally similar in all cases. However, there are still many unresolved issues. For instance, it is unknown whether all fusion reactions transit through hemifusion intermediates. Furthermore, it remains to be established whether the fusion proteins are either part of the initial fusion pores or at least directly influence their diameter and enlargement kinetics.

There is still only scant knowledge about the proteins involved in cell–cell fusion. Several candidate proteins were identified during the last years but in most cases it is not clear whether these proteins are primarily functioning in attachment rather than fusion. These include the tetraspanins CD 9 and CD 81, the single-pass membrane proteins of the ADAM family that may be involved in sperm-egg fusion, and the *Caneorhabditis elegans* protein EEF-1. Of these, EEF-1 is presently the strongest candidate for a bona fide fusion protein. It is both necessary and sufficient for cell–cell fusion, and it is structurally related to class II viral fusion proteins, containing an internal putative fusion peptide. Indeed, the search for cellular fusion proteins was driven for many years by the expectation that cellular fusion proteins must be similar

to viral fusion proteins. After all, viral fusion proteins must have originated from primordial eukaryotes.

Keywords

Capture Agents
An antibody or antibody mimetic that is immobilized on a surface for the purpose of binding an analyte of interest from a test sample.

Enzyme Activity Profiling
Determination of the activities of multiple enzymes in parallel, or of a single enzyme with respect to multiple substrates and/or potential inhibitors.

Multiplexed Protein Assay
An assay in which a single sample aliquot is simultaneously tested with respect to the abundance or activity of multiple proteins.

Protein Expression Profiling
Determination of the expression levels of multiple proteins in parallel and changes of expression levels.

Protein Interaction Profiling
Identification of the interactions between proteins and other molecules such as DNA, RNA, metabolites, or other proteins.

Protein Microarray
A two-dimensional surface with different antibodies or proteins attached at different defined locations, used for the study of the abundance or activity of proteins.

Protein microarrays allow for the parallel analysis of a large number of proteins with respect to their abundance or activity and, therefore, are playing an emerging role in proteome research.

Protein expression profiling, detection of enzymatic activity and protein interaction mapping are the most important applications of protein microarrays. The biological content, as well as the detection strategies, vary significantly between these applications, making the protein microarray technologies much more varied than those used with DNA microarrays.

In most cases, the biological content on the microarray, as well as the analytes, are proteins, which, due to their delicate nature and the heterogeneity of their properties,

complicate the manufacturing and assay design. The potential advantages of protein microarrays over nonparallel, macroscopic technologies cannot, however, be overestimated.

1 Introduction

Microarrays are miniaturized surface-based assay devices that allow for the multiplexed analysis of biological samples. In the case of DNA microarrays, which were developed in the 1990s, sequences of DNA are immobilized on a glass surface in a two-dimensional (2D) array format. These DNA microarrays are used for a number of applications in genome research.

In gene expression profiling, for example, differences in the expression levels of genes can be measured. DNA probes, each of which is composed of a sequence that is complementary to an mRNA sequence of interest, are immobilized on a glass surface in an array format. In order to detect different expression levels, mRNA from different biological samples is then extracted, amplified into cDNA and labeled with different fluorophores representing the different biological samples. Differences in gene expression can then be detected by an increase or decrease in fluorescence.

Today, DNA microarrays are commercially available and have been proven to be a very important tool in genomic research for the multiplexed comparative analysis of gene expression and gene polymorphism. Many important insights into gene expression patterns associated with disease states have been derived from such technology.

It is the proteins, however, that are the functional product of almost all genes, and mRNA levels correlate only weakly with protein levels. The measurement of mRNA also does not provide information about the activity or posttranslational modification of proteins. To gain a realistic understanding of biological systems, it is necessary to understand the expression and activity of the full complement of proteins in different biological systems.

Inspired by the power of DNA arrays to measure mRNA expression, several academic and industrial groups have created protein microarrays, with the aim of multiplexing and miniaturizing protein analysis. Protein microarrays allow researchers to quantify the abundance or activity of many proteins in parallel while expending minimal amounts of precious sample.

The main types of protein arrays are (1) expression profiling arrays, consisting of immobilized protein-capture molecules such as antibodies, which provide information about protein abundance; (2) functional arrays, consisting of arrays of correctly folded proteins, peptides or other molecules, which can be used to characterize enzymatic activities; and (3) protein interaction arrays, which can be used to characterize protein–protein, protein–DNA, protein–carbohydrate and protein–small-molecule interactions. Protein array technology has been developed to such an extent that it now has the requisite robustness, breadth, reproducibility, and flexibility to play a leading role in proteomics research.

2
Protein Microarrays for Protein Expression Profiling

2.1
Principle

The rationale for using protein arrays for expression profiling has been explained in the previous section, and can be justified by several studies showing that more information can be culled from the analysis of multiple molecular markers than could be obtained from analyzing individual ones.

The principle behind the construction of arrays for measuring multiple proteins in parallel is similar to that used in the construction of DNA arrays for multiplexed mRNA analysis. To construct DNA arrays, each feature is derivatized with a probe that hybridizes to a single mRNA species. The production of these DNA-based "capture agents" is relatively straightforward: one simply needs to design and synthesize a DNA sequence that is complementary to the mRNA that is to be measured. For protein arrays, however, there is no comparable method for creating capture agents using bioinformatics tools alone. Protein-capture agents – usually antibodies – must be developed experimentally, usually by immunizing an animal with the protein target and then isolating the resulting antibodies for immobilization.

The other major difference between arrays for measuring mRNA versus those for measuring proteins relates to how the captured analytes are detected. Captured nucleic acids can be labeled with fluorescent probes and directly detected using a confocal fluorescence scanner. Proteins in a sample can also be directly labeled, but the process is much less reproducible than is the labeling of nucleic acids. Alternatively, proteins captured on an array can be indirectly detected by the use of labeled antibodies that recognize a different epitope on the captured target proteins. These and other issues regarding the development of the biological content for expression profiling applications are discussed in the following section.

2.2
Content for Protein Expression Profiling Chips

Most protein-profiling platforms rely on "sandwich pair" reagents – two different antibodies that can simultaneously bind to a target protein. For each target protein, one of these antibodies is immobilized onto the array, and the other one, which contains a label, is used to detect the target protein that has been captured on the array (Fig. 1). The principle behind the sandwich assay, and its advantages, are discussed in Sect. 2.4.

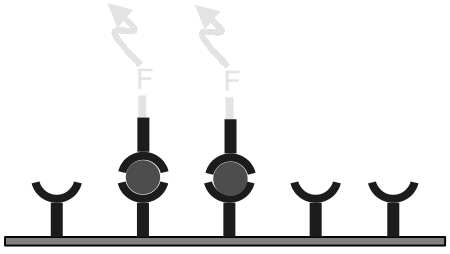

Fig. 1 Principle of a sandwich assay. A capture antibody is immobilized on a solid support. The captured analyte is detected using a second, fluorescently labeled antibody.

2.2.1 Source of Antigen

The first step in developing such sandwich pairs is usually to express and purify significant amounts of the target protein in a form as close as possible to its native state. This task can require as much, if not more, work than creating the capture agents themselves. Most proteins of interest need to be expressed in systems such as mammalian or insect cells, which require the investment of considerable time and cost. Most mammalian proteins are misfolded and insoluble when expressed in bacteria, and refolding protocols need to be individually tailored to each protein. The possibility of forgoing protein production altogether by using peptide antigens is rarely successful since most of the resulting antibodies have insufficient affinity against native proteins.

There are several sources of cDNAs for cloning into expression vectors, such as the NIH Mammalian Gene Collection, the Harvard Institute of Proteomics, the IMAGE Consortium, and the American Tissue Culture Collection (ATCC), and private companies such as Open Biosystems (Huntsville, AL) and Invitrogen (Carlsbad, CA). Modern cloning methods that avoid the use of restriction enzymes and contain various characteristics that favor correct insert orientation can make the cloning as high throughput and generic as possible. Multihost vectors and recombination-based transfer systems allow for the production of target proteins, including purification and detection tags for expression in multiple hosts. The first step is to transfer the gene into a ''transfer'' or ''donor'' vector and confirm its sequence; in the second step, the insert is shuttled into vectors for expressing the proteins in mammalian or insect cells. Both Invitrogen (Carlsbad, CA) and BD Biosciences Clontech (Palo Alto, CA) have commercialized such systems. The inclusion of N- or C-terminal purification tags in the encoded constructs allow for ''generic'' purification systems. The use of two affinity tags, such as the His tag plus the Glutathione-S-transferase (GST), or FLAG tag, can result in >95% pure protein using generic operating procedures.

For proteins that are large or contain important posttranslational modifications, it is often necessary to use expression systems based on higher eukaryotes. Recent improvements in technologies for introducing DNA constructs into cells, either virally or through transient transfection, have allowed for yields of up to 50 mg L^{-1} in mammalian cells or even higher in baculovirus-infected insect cells.

2.2.2 Types of Protein-binding Agents

Monoclonal antibodies (mAbs) are the most commonly used protein-binding agents for protein expression profiling platforms since they are monospecific and can be produced in unlimited quantities at low cost once a hybridoma cell line is developed. In some cases, proteolytic fragments of antibodies (Fabs) are used, since these can give improved performance due to the fact that an oriented presentation of the binding agent is possible. For sandwich-based approaches, the capture agent is almost always a mAb but the detection agents are occasionally polyclonal antibodies.

Monoclonal antibodies used in protein biochips should have dissociation constants (K_D) in the single-digit nanomolar range. Lower affinity antibodies generally have rapid ($>10^{-3}$ s^{-1}) dissociation rates (k_{off}), which result in the loss of the vast majority of captured antigen during the assay steps of washing and (in the

case of sandwich assays) incubation with detection antibodies. Capture antibodies should preferably have $k_{off} < 10^{-4}\ s^{-1}$ and $K_D < 10^{-10}$ M. It usually requires repeated attempts at immunization to obtain such reagents.

Polyclonal antibodies are generally poorly suited as capture agents for protein biochips because only 0.1 to 10% of the antibodies in a preparation are specific to the immunogen used to create them. The only way to improve on this is to affinity-purify the antigen-specific antibodies away from the bulk immunoglobulin, but this requires large amounts of antigen, and such affinity-purified polyclonal antibodies cannot compare to mAbs in terms of homogeneity and lot-to-lot consistency. For these reasons, polyclonal antibodies instead find a more suitable role as the detection agents in multiplexed platforms using arrays of mAbs. In the detection step, the captured antigen will be selectively targeted by the highest affinity antibodies in the polyclonal preparation, and the fact that >95% of the antibodies in this preparation have limited or no affinity to the antigen is relatively unimportant.

The high expense and slow nature of mAb development has inspired the invention of alternative methods for making antibodies and antibody mimetics. Display technologies in which recombinant antibody fragments are linked to the genetic information encoding them are increasingly used. Such systems include phage display, ribosome display, mRNA display, yeast display, and bacterial display. The displayed libraries are usually in a Fab or single-chain variable region (scFv) configuration, the latter of which is less suitable due to its instability and conformational heterogeneity, which leads to lower affinities toward antigens. Artificial libraries of ''antibody mimetics'' have been created in which certain surface loops of nonantibody proteins are replaced by random sequences to make artificial complementarity-determining regions (CDRs). Although there have been several demonstrations of the creation of high-affinity protein-binding agents from naïve libraries using display methods, typical dissociation constants are in the 10^{-6} to 10^{-8} M range and therefore not suitable for multiplexed protein analysis platforms. Another drawback of these methods is that antibody fragments are significantly more expensive to manufacture than traditional mAbs.

Perhaps the most radical approach for creating the protein-binding agents is to use nucleic acid–based molecules. Libraries of random nucleic acid sequences can be subjected to systematic evolution of ligands by exponential enrichment (SELEX) to identify ''aptamers'' – rare single-stranded molecules that fold into a structure capable of binding to protein targets. Arrays of aptamers can be used to create protein expression profiling arrays. ''Photoaptamers'' are bromodeoxyuridine-substituted DNA molecules that can photocrosslink to their target proteins. The photo-crosslinking event provides a second dimension of specificity since it requires close juxtaposition of reactive groups. The covalent crosslink allows for stringent washing of the arrays to remove nonspecifically bound proteins. Nonspecific protein-reactive dyes can be used to detect the captured proteins on the arrays. Photoaptamers can crosslink low picomolar concentrations of target proteins with very high specificity, even in the presence of high concentrations of noncognate proteins from serum. A fluorescent image of a photoaptamer array is shown in Fig. 2.

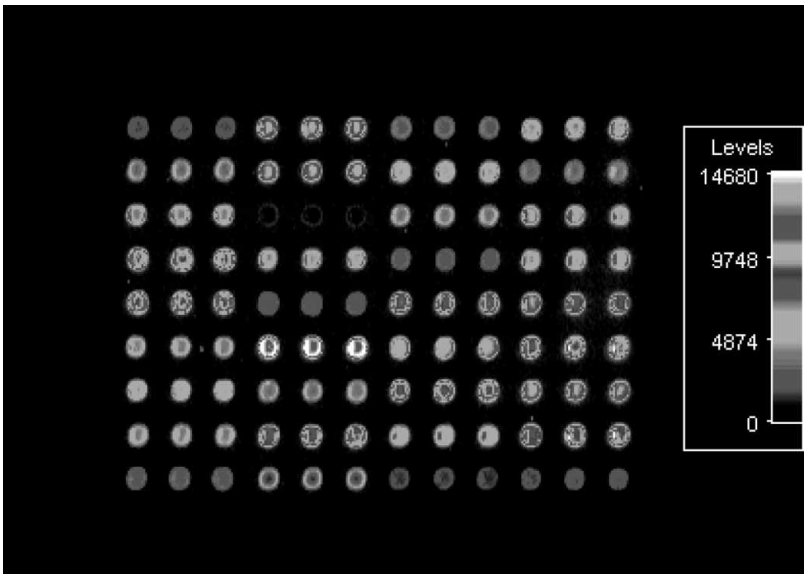

Fig. 2 Example of a photoaptamer array. Universal protein stain (UPS) photoaptamer array for the simultaneous assay of 26 analytes. The array was exposed to 10% human serum. After photo-crosslinking, the array was washed and stained with Alexa 647 dye and read on a TECAN LS300 scanner. (Figure courtesy SomaLogic Inc).

2.3 Protein-immobilization Methods

Proteins are very fragile molecules that are easily denatured at liquid–solid and liquid–air interfaces, and therefore the nature of the surfaces to which proteins are attached, as well as the dispensing method, can have pronounced effects on the surface protein density and the fraction of immobilized protein that is active. This section discusses dispensing methods and surface chemistries used for two-dimensional protein arrays.

Three approaches to protein immobilization are in common use.

Physical adsorption. The easiest way to immobilize proteins is by physical adsorption to surfaces with inherent nonspecific protein-binding activity. The surface-binding energy is hydrophobic in nature when using materials such as plastic, or electrostatic in nature when using charged surfaces such as polylysine-coated glass or nitrocellulose. A protein film is spontaneously formed on such surfaces when brought into contact with a protein solution, making this the simplest procedure for creating arrays. In such films, each protein is attached via multiple weak noncovalent interactions, but since the overall interaction surface on each protein is large, the sum of these weak interactions results in binding energies that are orders of magnitude stronger than typical specific protein–protein interactions. The main disadvantage of these approaches is that the interaction energies are so great that they frequently denature or otherwise inactivate the immobilized proteins. Generally, 75 to 90% of proteins attached to surfaces in this way are inactivated.

Random chemical attachment. The second most facile protein-immobilization method is based on random covalent attachment of proteins to substrates. Most methods take advantage of the fact that proteins typically contain several surface-exposed lysine residues. The amino group on the lysine side chains can react with surfaces containing, for example, *N*-hydroxysuccinimide moieties. The random chemical coupling results in heterogeneity with respect to the number of crosslinking sites per protein, the position of the crosslinks, and, as a result, the orientation of the proteins with respect to the surface. Many of the proteins are therefore inactivated by modification, by inaccessibility of the binding site, or by denaturation arising from strain caused by multiple attachment sites. A variation on this theme relies on random chemical biotinylation of lysine residues followed by exposure to streptavidin-coated surfaces.

Site-specific attachment. Optimal protein activity-retention is achieved by using single point oriented surface attachment of the binding agents. The most facile way of achieving this is to conjugate a binding agent through a unique cysteine residue that is either naturally present or has been introduced by genetic engineering. Surfaces can be derivatized by a number of thiol-reactive functionalities such as maleimide. Coupling can be made to occur almost exclusively to the thiol group on the unique cysteine, giving homogeneously oriented binding agents. Several studies have demonstrated the superior performance of protein arrays made using this method. Alternatively, the glycosylated functionalities on the Fc region of antibodies, which is distal from the antigen-binding site, can be used as an immobilization handle. Recombinant proteins can also be attached to surfaces in an oriented fashion by incorporating affinity tags such as the hexahistidine tag or the biotin-accepting peptide, which can be enzymatically biotinylated. These tags allow for the oriented immobilization on surfaces coated with Ni-complexes or streptavidin.

The choice of methods for immobilization depends highly on the sensitivity required in the assay and the number of binding agents that will be immobilized. For example, the amount of work involved in creating protein arrays with site-specifically attached proteins may not be justified when the number of proteins is high. Alternatively, arrays of 10 to 20 proteins in which a 2 to 5-fold increased sensitivity would be highly valued would justify the added effort required to create arrays with specifically oriented binding agents.

Flat surfaces have an inherent limitation on the number of protein molecules that can be immobilized per unit area. To extend beyond this limit, one must build a brush or gel structure onto the surface and attach the proteins to it. One theoretical drawback to this approach may be poor penetration into and out of the structure, leading to slow equilibration times and high nonspecific binding. This approach led to the commercialization of a ''hydrogel'' slide based on polyacrylamide, now sold by Perkin-Elmer Life Sciences (Foster City, CA). Slides such as these have been shown capable of immobilizing active proteins at a density at least fivefold higher than is possible using optimized flat surfaces. Another advantage is that the hydrogel can protect proteins from dehydration and therefore provide for a higher specific activity.

2.4 Detection Techniques

Nearly all reports of protein arrays rely on detection by fluorescence or chemiluminescence. Charge-coupled device-based cameras or laser scanners with confocal detection optics are commercially available. The proteins in a biological sample can be directly labeled with fluorescent dyes or with biotin, captured by the binding agents on the features of the array, and then detected using such fluorescent scanners (Fig. 3). To compare expression patterns between two different samples, each of the two samples is labeled with a different fluorescent dye. After labeling, the two samples are mixed together and then exposed to the array. A confocal fluorescence scanner then quantifies the signal from the two dyes (typically Cy3 and Cy5). However, such methods generally have very poor sensitivity for the following reasons: (1) fewer labels can be conjugated per protein without causing loss of solubility than for nucleic acids; (2) many proteins in samples are prone to nonspecific binding to surfaces, resulting in high background; and (3) different proteins are labeled with different efficiencies, usually relating to the number of accessible lysine residues. Owing to these reasons, chemical labeling of proteins has very limited applications for protein arrays.

Orders of magnitude higher sensitivity and reproducibility can be obtained with the use of ''sandwich pair'' antibodies (Fig. 1). In this case, two different antibodies, reacting to different regions (epitopes) of the target protein, are exploited. One antibody – the ''capture agent'' – is immobilized onto the array feature and captures the target protein; the other one – the ''detection agent'' – carries a label and binds to the captured target protein, forming a ''sandwich'' around it. The use of two antibodies greatly increases both the absolute amount of signal per captured target protein (since the detection antibody can be derivatized with very bright labels such as phycoerythrin), as well as the specificity of the signal (since two antibody-target protein-binding events must occur to produce signal). Such an assay format has the additional advantage of lending itself to high sample throughput since the biological sample need not be chemically labeled. The disadvantage of the use of sandwich reagent pairs is that two antibodies, both of which must recognize the target protein in its native form, must be developed and validated.

The sensitivity of sandwich assays can be pushed to new limits by amplifying the signal from the detection antibody using rolling circle amplification (RCA). To accomplish this, the detection antibody is labeled with a DNA primer annealed to a circular DNA template. Upon localization of the detection antibody on the array, the DNA primer on the antibody can be extended by a DNA polymerase on the circular template. Since the template has no end, the polymerase creates very

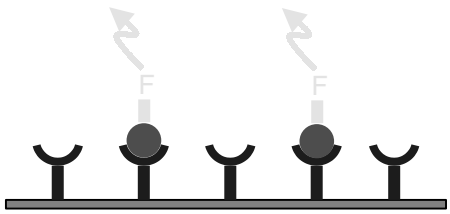

Fig. 3 Fluorescently labeled proteins are captured on an antibody array.

long DNA products in a ''rolling circle amplification'' reaction. Hybridization of fluorescently labeled oligonucleotides to this DNA product leads to a high density of fluorophores on the feature. Using this approach, it is possible to detect dozens of cytokines in parallel in the low picomolar range.

Another strategy for the fluorescent detection of proteins on array surfaces is to use planar waveguide technology in conjunction with fluorescently labeled detection antibodies. In this case, only the surface-bound fluorescently labeled molecules are detected, so no washing step is required. This allows one to take measurements under equilibrium conditions, thus avoiding the time-consuming array-washing steps.

In contrast with fluorescence and other optical readouts, mass spectrometry (MS) provides information as to the molecular weights of the captured proteins. The most widely used system relies on matrix-assisted laser desorption–ionization (MALDI) or surface-enhanced laser desorption–ionization (SELDI). The target proteins are captured by surface immobilized antibodies. One limitation of this system is the relatively low sensitivity in comparison to sandwich assay–based methods and the need to treat the surface-captured proteins with proteases prior to MALDI analysis. It is also difficult to obtain quantitative data on the basis of a purely MS-based approach.

2.5 Applications

2.5.1 Antibody Arrays

Antibody arrays have been used to monitor relatively small numbers of proteins in parallel, mainly due to the lack of developed antibody content for these platforms. Most arrays investigating >100 specificities have relied upon direct sample labeling since there are few proteins for which high quality sandwich pair antibodies are available. Generally, the two-dye labeling method mentioned above is used to compare two different samples. Several groups have analyzed changes in protein expression among cells as they become cancerous, or progress through different cytological stages, or are exposed to radiation.

Protein expression changes have been identified in squamous cell carcinoma, for example, with the aid of laser capture microdissection to separate out the different cell types prior to sample labeling. Samples were applied to an array of 368 antibodies against known signaling proteins. Eleven different proteins were identified that changed expression levels, some of which were in the cancer cells and others were in the surrounding stroma. A similar approach of combining laser capture microdissection with antibody arrays to find cancer biomarkers was used to study hepatocellular carcinoma. Antibodies to 83 proteins likely to be involved in proliferation made up the array, and differences in expression were observed for 32 of them. The data was confirmed by the use of western blots and tissue microarrays.

Most published reports of protein expression profiling arrays focus on a smaller number (10–75) of specificities, generally all within a restricted class of proteins, and use sandwich-based antibody pairs for detection. One high-density array that allowed for the measurement of expression levels of 75 cytokines was constructed. Similar products have been reported, but with a smaller number of specificities. Such cytokine-detection arrays have made it possible to uncover the complex changes in cytokine abundance that result from exposure to proinflammatory factors such

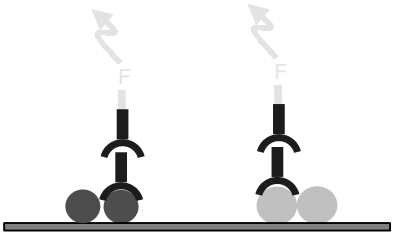
as lipopolysaccharide or tumor necrosis factor-α. Similar arrays have also delineated differences in cytokine production between TH1 and TH2 helper cells, as well as uncovered an unexpected relationship between vitamin E levels and the cytokine monocyte chemoattractant protein-1.

In another study, the relationship between 78 inflammatory mediators and cerebral palsy was studied. Cord blood from 19 cerebral palsy children and 19 gestation matched controls were analyzed and significant differences were observed in the expression of 11 of the 78 proteins studied. In addition, it was found that cord blood from preterm infants with cerebral palsy showed even more elevated levels of certain inflammatory mediators than the gestation matched controls.

2.5.2 **Antigen Arrays**

Antigen arrays, sometimes referred to as *reverse arrays,* are used to measure the levels of antibodies with defined specificities in serum. Proteins of interest, allergens, or proteins known to elicit an autoimmune response are arrayed on a substrate. Serum samples of patients are applied, allowing the antibodies from the patient to bind to the arrayed proteins, if antibodies with such binding specificity are present. Then, a fluorescently labeled antihuman antibody–antibody is added to reveal which types of antibodies are present in the serum (Fig. 4).

Antigen arrays have been successfully applied to the fields of allergy, autoimmune disease, and inflammation. An array of 430 distinct proteins and overlapping peptides that represent the simian-human immunodeficiency virus (SHIV) proteome, for example, was used to analyze serum from vaccinated and nonvaccinated primates after challenge with SHIV. It was observed that the vaccinated versus nonvaccinated animals could be distinguished and survival predicted. A



(a)

(b)

Fig. 4 Scheme and example of an antigen array. (a) Antigens are arrayed on a two-dimensional surface. Autoantibodies in serum are captured and detected with a fluorescently labeled antihuman antibody-antibody. (b) ''Arthritis Array'' characterization of autoantibodies in systemic lupus erythematosus. Arthritis arrays were produced by printing common lupus antigens including DNA, histone proteins, and additional nuclear proteins on microscope slides. Arrays were incubated with patient serum, and binding of autoimmune antibodies was detected with green fluorescent markers (green spots). The yellow spots are used as ''marker features'' to orient the arrays. (Figure courtesy Dr. William Robinson, Stanford University) (see color plate p. xxix).

second study used an array of proteins and peptide fragments representing all the known proteins in myelin to monitor autoantibody development in experimental autoimmune encephalomyelitis, a model for multiple sclerosis.

Antigen arrays were used to profile antibodies from patients diagnosed with various rheumatoid diseases, including rheumatoid arthritis, systemic lupis, systemic sclerosis, and Sjogrens syndrome. A characteristic autoantibody pattern for each of the diseases was observed, giving hope that such an array could be used as a diagnostic and monitoring tool.

It is well known that cancer patients often develop antibodies against proteins expressed in their tumors. In an effort to use such immunological information in the diagnosis of cancer, Qiu and colleagues fractionated protein lysates from a human lung cancer cell line and then arrayed them onto nitrocellulose-coated slides. The serum from individuals with or without lung cancer were then applied to the arrays to visualize the autoreactivity to cancer antigens. The signals from duplicate spots (within-slide) and duplicate slides were highly reproducible, exhibiting correlation values >0.9. Of the 1840 arrayed fractions, 63 demonstrated increased reactivity in cancer patients relative to normal, as measured by a rank-based statistic ($p < 0.008$). This type of approach, or one based on arraying purified cancer antigens, may be useful in the future in the identification and classification of patients.

2.6 Alternative Technologies

To increase the sample throughput and still maintain at least a modest degree of multiplexing, several groups have constructed antibody arrays within the wells of microtiter plates, generally containing 96 wells/plate. In such cases, the readout is typically based on a sandwich assay in which the detection antibodies are labeled with an enzyme that catalyzes a reaction to form locally precipitating fluorescent or chemiluminescent products. A commercial system for cytokine analysis has been commercialized by Pierce (Rockford, IL).

A more radical departure from the array configurations considered in the previous chapters is the so-called ''liquid array'' – suspended, encoded particles, each coated with a single antibody specificity. The most common way to encode beads relies on the incorporation of different ratios of two or more fluorophores with distinguishable spectral properties. A flow cytometer is exploited to read particles one at a time, thus decoding the identity of each particle (and thereby the identity of the immobilized antibody), while simultaneously reading a third fluorescent signal that represents binding of the target protein. This third signal is generally produced by the binding of a detection antibody labeled with the strongly fluorescent protein phycoerythrin, in a sandwich setup. The most popular suspension array platform is marketed by Luminex (Austin, TX). Several companies sell kits for multiplexed detection of cytokines and other proteins. Instruments and reagents are also available commercially to allow researchers to construct their own liquid arrays. Some of the key similarities of the liquid versus the more standard two-dimensional array platforms are shown in Table 1. The key advantages of the liquid array system are as follows: (1) manufacturing is easier since antibodies can be incubated in batch mode with the beads, thus overcoming difficulties in reproducible spotting due to denaturation, evaporation, and so on; (2) commercial systems are already

Tab. 1 Comparison of multiplexed protein analysis platforms.

	Two-dimensional arrays	*Suspended particle arrays*
Assay type	Direct capture, sandwich assay, functional assays	Direct capture, sandwich assay
Array construction method	Robotic spotting	Batch incubation of encoded particles with antibodies followed by particle mixing
Detection	Fluorescence, radioactivity, SPR, mass spectrometry	Fluorescence
Multiplexing	High	Medium
Sample throughput	Low	High
Storage	Dry	In buffer

available for fully automating the assay procedure; (3) ability to ''mix and match'' beads with a variety of specificities, as needed; and (4) compatibility with microtiter plates, since samples are loaded from 96-well plates and instruments can analyze an entire plate of samples in less than one day. Because of these advantages, the liquid array systems are becoming more popular and useful in life sciences than the two-dimensional arrays and will continue to be so for multiplexing applications in which the number of specificities is <100 and when sample throughput is important.

There are numerous publications using liquid arrays for multiplexed protein expression profiling, mostly involving the measurement of a limited number of cytokines or other secreted signaling molecules. One example is the measurement of cytokines in the serum of children infected with rotavirus. Three cytokines showed significantly higher expression levels in infected children. In another study, Soldan and colleagues profiled seven cytokines from stimulated peripheral blood mononuclear cells from females with relapsing-remitting multiple sclerosis (RRMS), and secondary progressive multiple sclerosis (SPMS). Two cytokines were significantly different between the RRMS and SPMS patients, which may indicate therapeutic directions for treating these two ailments.

3 Protein Microarrays for Enzyme Activity Profiling

3.1 Principle

Although it is of great value to determine the abundance of proteins in complex biological systems, it is also important to measure the enzymatic activity of proteins. Kinases, for example, play an essential role in almost all signal transduction processes in cells. The multiplexing capability of microarrays is especially suited for these screening efforts.

Two microarray formats are most commonly used for enzyme activity screening. In one case, the substrates of enzymes such as kinases or proteases are immobilized (Fig. 5a). The reaction can be monitored by a variety of different detection strategies that depend on the modification. If used for the determination of enzyme abundance, this format can also lead to

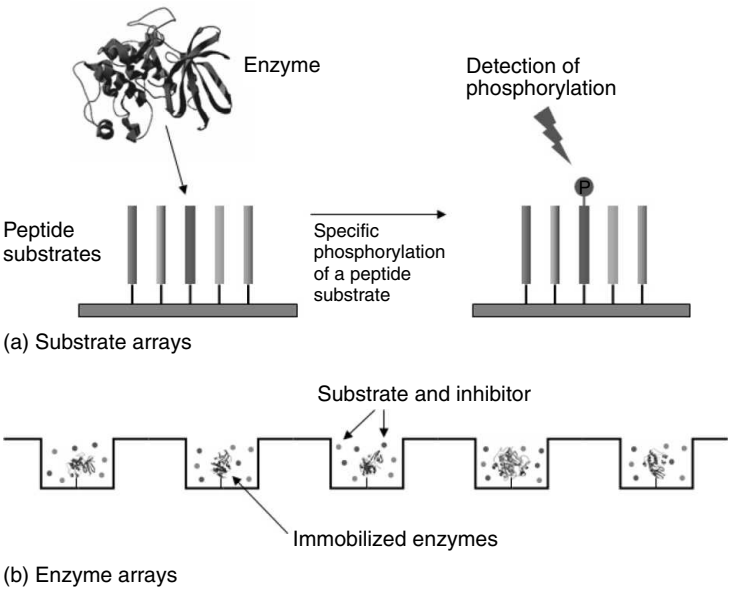


Fig. 5 The two most common formats for enzyme activity screening on microarrays. (a) Substrates, in this case of kinases, are arrayed on a surface, and their modification by enzymes detected. (b) Enzymes are immobilized, typically in nanowells, and their activity is measured by incubation with substrates in the absence or presence of inhibitors.

improved sensitivity, as the enzyme abundance is measured by its activity, which only requires the presence of a specific substrate and not through its binding to an immobilized capture agent, in which case the sensitivity depends on the affinity.

In the other case, an array of enzymes is prepared and their activity detected at their location, usually in a nanowell format (Fig. 5b). This format can also be used for inhibitor screening.

3.2 Immobilization of Enzymes or their Substrates

As in the case of protein-profiling microarrays, the immobilization strategy is also a key feature for the sensitivity and reproducibility of enzyme assays in microarray formats. The advantage in the manufacturing of peptide or small-molecule arrays, however, is the lack of complex and environmentally dependent three-dimensional structures of these molecules as compared with proteins. To ensure reproducibility and allow for a quantitative comparison of results across microarrays, however, it is still crucial to immobilize peptide substrates in an oriented and uniform fashion.

Peptide substrates for enzyme activity screening can be readily produced in a high-throughput fashion by solid-phase synthesis, which also allows for the incorporation of a variety of functional groups for covalent surface attachment. Several elegant approaches for covalent immobilization have been developed using different reaction schemes (Table 2).

Tab. 2 Selected reactions for the covalent immobilization of peptides on surfaces.

Functional group in substrate	*Functional group on surface*	*Reaction product for immobilization of substrate on surface*
 Alkoxyamino group	 Aldehyde group	 Oxime group
 1,2-Aminothiol group	 Aldehyde group	 Thiazolidine group
 Cysteine group	 Thioester group	 Amide group

(*continued overleaf*)

Tab. 2 (*Continued*)

Functional group in substrate	*Functional group on surface*	*Reaction product for immobilization of substrate on surface*
Substrate  Biotin group	Avidin – surface	High-affinity interaction between avidin on the surface and biotin in the substrate
Substrate  Cyclopentadiene group	 Benzoquinone group	 Bicyclic group
 NHS-activated ester group	H_2N —— Surface Amino group	 Amide group

An advantage of these approaches is the oriented immobilization, thereby decreasing the fraction of peptides that are immobilized in an orientation that inhibits their participation in the enzymatic reaction.

Another approach towards manufacturing peptide arrays is the direct synthesis of the peptides on surfaces. In the so-called SPOT synthesis, reaction reagents, together with the amino acid monomers, are spotted onto a supporting membrane, such as cellulose, allowing for the construction of arrays with about 100 sequences/cm^2. An additional on-chip peptide synthesis method has been described by Gao and coworkers, which uses t-Boc-based chemistry to generate acids on the surface by photolithography for spatial deprotection of the amino acids during the synthesis process.

Nitrocellulose has been used to create arrays, not only of proteins, but also of peptides. This surface, like many others, has a very high nonspecific protein-binding tendency, which can however, interfere with assays. Bovine serum albumin (BSA) is a very common blocking agent in protein microarray assays to minimize nonspecific protein binding to microarrays surfaces. In peptide microarrays, however, it can mask the much smaller peptides and prevent enzymes from gaining access to them. The use of oligo(ethylene glycol) groups on the surface has proven to be very useful in the prevention of nonspecific adsorption. These groups can also act as a linker between the surface and the immobilized peptides. Another approach exploits the nonspecific adsorption of BSA onto surfaces such as glass; the film of BSA can then be modified by attaching *N*-hydroxysuccinimide groups that can react with amino groups on the peptide substrates.

In cases where the enzyme, rather than the substrate, is arrayed, it is often necessary to create a diffusion boundary between the different features of the array; as a result, any modified substrate remains associated with the feature containing the arrayed enzyme. Fabricated chips with microwells containing covalently attached kinases or proteases have been used to characterize the specificity of enzymes and to identify inhibitors. In this case, the assay strategy is very similar to plate-based enzyme assays, in which the enzyme is incubated with its substrate in the presence of different inhibitors and the extent of substrate modification is an indication of the inhibitory potential of the inhibitors.

3.3 Detection of Enzymatic Activity on Microarrays

The strategy for detecting enzymatic activity on a microarray depends on the nature of the catalyzed reaction. To profile proteolytic or otherwise hydrolytic reactions, one can take advantage of the reaction releasing an immobilized fluorescent dye from the substrate. Coumarin-based derivatives are the most commonly exploited dyes for such studies and have been used to monitor proteolysis of peptide substrates (Fig. 6).

Kinase activity results in a phosphorylation of a specific target sequence in a peptide or protein substrate on the microarray. Such a reaction requires the presence of a cosubstrate such as ATP, from which the phosphate group is transferred to the substrate on the surface. A very sensitive approach for the detection of phosphorylation events is to use radioactive [γ^{32}P]-ATP and quantify the amount of radioactive phosphate transferred to different arrayed

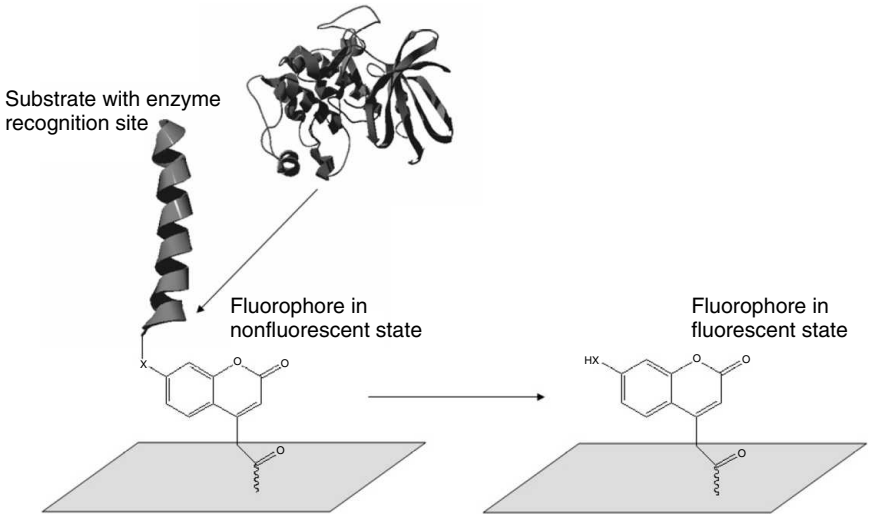

Fig. 6 Detection of protease activity on microarray surfaces with fluorescently labeled peptide substrates. The peptide substrates are immobilized on the array surface with fluorophores adjacent to the enzyme recognition site. Cleavage releases the peptide substrate and the immobilized fluorophores become fluorescent.

substrates using phosphorimaging analysis or autoradiography. Because these detection methods suffer from low spatial resolution, an alternative is to apply a photographic emulsion directly to the arrays (after the enzymatic phosphotransfer reactions were complete), and visualize the results by light microscopy.

Owing to the inconvenience and potential health hazard of working with radioactivity, nonradioactive alternatives to the detection of phosphotransfer reactions on arrays can also be applied. Phosphorylated peptide substrates can be detected using fluorescently labeled antiphosphopeptide antibodies. The universal application of this technique compared with radioactive detection, however, is problematic, as the affinity of antibodies varies depending on the phosphoamino acid sequence context. Another possible detection strategy for kinase microarray assays exploits the use of phosphospecific fluorescent dyes; such dyes are used in gel electrophoresis for the detection of phosphorylation.

Figure 7 summarizes the different detection technologies for kinase activity arrays.

3.4 Applications

Microarrays of substrates or enzymes are becoming increasingly important for the characterization, abundance determination and inhibitor screening of enzymes. Perhaps because it is far easier to array the substrates than the enzymes themselves, most published applications to date describe peptide microarrays used to detect protease or kinase activity. Mrksich and coworkers, for example, developed a peptide chip used to characterize inhibitors of the nonreceptor tyrosine kinase c-Src. The chip was prepared by immobilizing the kinase substrate onto a self-assembled

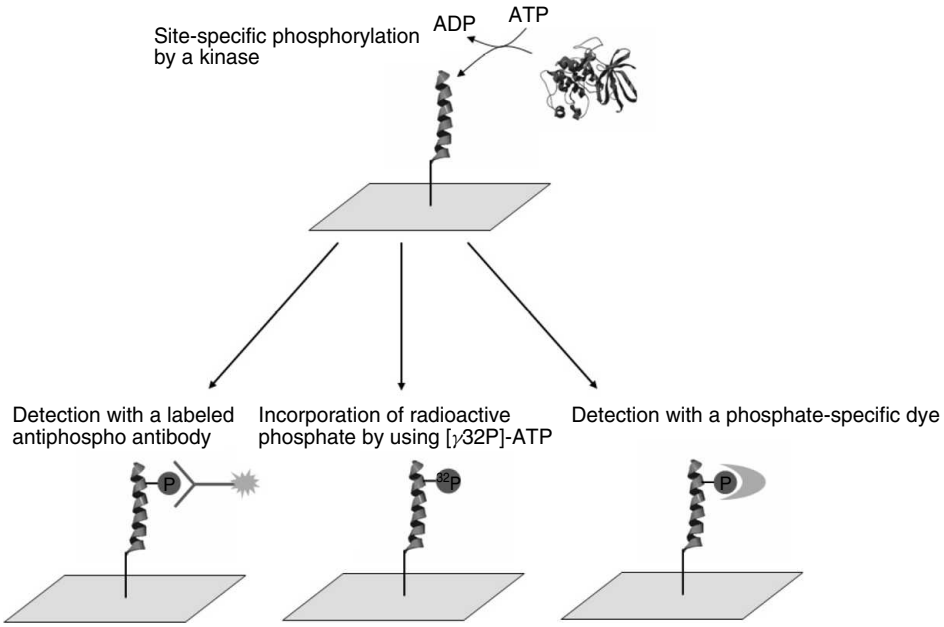

Fig. 7 Overview of the different detection technologies for kinase activity arrays.

monolayer of alkanethiolates on gold. Phosphorylation of the immobilized peptides was characterized by surface plasmon resonance, fluorescence, and phosphorimaging. Three inhibitors of the enzyme were quantitatively evaluated in an array format on a single, homogeneous substrate.

Most applications that have been described so far, however, are proof-of-concept studies evaluating either the immobilization or the detection strategies that have been described above. Examples of these applications to characterize kinases or proteases with substrate microarrays can be found in the list of the primary articles listed at the end of this chapter.

Novel microwell-based protein chip technology for high-throughput analysis of biochemical activities has also been described for the analysis of nearly all protein kinases from the yeast *Saccharomyces cerevisiae*. Of the 122 known and predicted yeast protein kinases, 119 were overexpressed and analyzed using 17 different substrates. Studies of this nature have shown that many novel activities can be identified and that a large number of protein kinases, not known to be capable of phosphorylating tyrosine peptide sequences, do possess this biochemical activity.

3.5 Alternative Technologies

The advent of microarrays for enzyme activity profiling has made tremendous progress in the last few years, as reflected by the number of recent publications, especially concerning peptide microarrays for kinase activity profiling and protease fingerprinting. The use of this technology in industrial research, however, is still limited

owing to the fact that most laboratories today perform assays in 384- or 1536-well plates, and existing automation technology facilitates high-throughput screening. Such plate-based assays do not require as much technology and assay development as surface-based setups.

One interesting alternative to microarrays for multiplexing the analysis of enzymatic activity was reported by Kozarich, who applied the principles of enzyme chemistry, mechanism of action and inhibitor design to create a set of activity-based probes. The use of suicide inhibitors allows for interrogation of enzyme family members, both known and unknown, in cells and protein extract fractions without the need for individual assay development and isolation. The serine hydrolases and cysteine proteases have provided the proofs of concept for this type of activity-based proteomics platform, and other studies are rapidly following.

4
Protein Microarrays for Protein Interaction Profiling

4.1
Principle

The interactions of proteins with each other and with other molecules constitute an essential component of all biological processes. In addition to the profiling of enzymatic activity, functional proteomics is therefore also focused on the elucidation of protein interaction networks, also called protein interaction maps. Different research groups, using different methods, however, often report conflicting results, emphasizing the importance of using a variety of methods in order to verify results.

Because of the complexity of these networks and the large number of interactions, high-throughput methods are essential for generating comprehensive data sets on any of the critical pathways controlling biological events. Microarrays are ideally suited for the parallel analysis of thousands of interactions of proteins with each other and with other key metabolic and regulatory molecules such as DNA, RNA, lipids, carbohydrates, metabolites, and allosteric effectors. Most of the reports on the use of protein microarrays for interaction profiling have, to date, focused on the interaction of proteins with non-protein molecules. The main reasons for this are (1) high-throughput methods already exist for studying protein–protein interactions, most notably the yeast two-hybrid system and (2) the difficulty in creating and purifying large collections of active proteins (as discussed in Sect. 2.2.1) in comparison to the relative ease of producing small molecules, peptides, RNA, or DNA.

The on-chip detection of substances, whether proteins or other molecules, that bind to the proteins on the arrays poses an additional challenge. If the analyte contains a complex mixture of molecules, it is not trivial to identify which ones are binding to the arrayed proteins. In the simplest case, for example, the analyte contains only one substance that is labeled by a fluorescent group–in which case the readout is straightforward (Fig. 8).

The used label is usually very similar to the ones that were described in Chapter 2 for protein expression profiling microarrays.

4.2
Applications

To date, at least one whole proteome microarray has been developed, consisting of

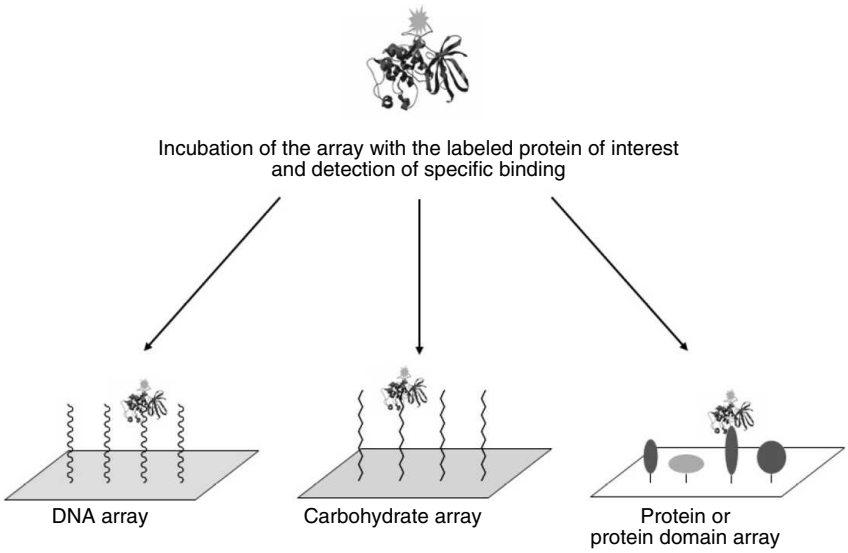

Fig. 8 Principle of a protein interaction microarray.

almost the entire yeast proteome on a chip. High-throughput protein expression and purification methods are critical for the success of such endeavors. To establish such a proteome microarray, open reading frames encoding the proteins must be cloned into an expression vector that allows for the production of fusion proteins with affinity tags that can be used in high-throughput purification (e.g. GST tag for purification on glutathione columns) and immobilization (e.g. His tag for immobilization on Ni^{2+}-nitrilotriacetic acid (Ni-NTA), coated glass slides). These proteome microarrays can then be probed, for example, with biotin-labeled proteins or other molecules and the interactions detected by adding fluorescently labeled streptavidin.

More commonly, a subset of proteins from an organism, defined by a protein or disease class are immobilized and then probed for interactions.

An elegant approach for alleviating the difficulties with fabrication of protein microarrays, as opposed to the relatively straightforward methods for arraying DNA, is the following: DNA sequences encoding proteins of interest, genetically fused to an immobilization tag, are incubated in a cell-free expression lysate on a tag-binding surface. Proteins are synthesized *in situ* and directly immobilized by the interaction of the tag with the surface (Fig. 9).

Despite these efforts, the high-throughput production of correctly folded proteins still poses an obstacle in the fabrication of protein microarrays (Sect. 2.2.1). One way to alleviate this is to synthesize and immobilize smaller, functional domains of proteins that are responsible for a specific activity or interaction. The so-called SPOT synthesis, for example (see Sect. 3.2), has been used for the preparation of microarrays of protein domains that can then be probed for interaction with target molecules.

Protein–DNA interactions are crucial for the regulation of gene transcription and DNA replication. The fact that the methods for the construction of DNA microarrays are well established makes

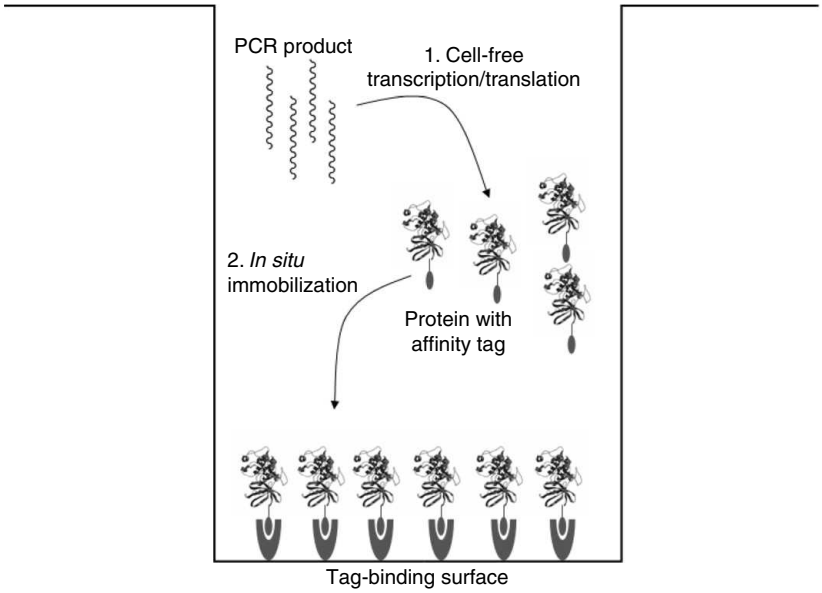

Fig. 9 Example of *in situ* immobilization of proteins on surfaces by the DiscernArray™ technology described by He and colleagues.

them an ideal tool for the screening of DNA–protein interactions. This approach can, for example, be used to screen the interaction of transcription factors or DNA-modifying enzymes.

Carbohydrates constitute another important class of molecules that interact with proteins. Advancements in the synthesis of carbohydrates, as well as carbohydrate-compatible immobilization strategies, led to the first manufacturing of arrays in 2002 and established carbohydrate microarrays as an important tool in ''glycomics.'' Carbohydrates can be immobilized on microarray surfaces and remain accessible to interacting with proteins. The application of carbohydrate arrays to answer important biological questions has been demonstrated by Seeberger and coworkers, who used them to characterize the binding specificity of different gp120-binding proteins, important for HIV entry into host cells.

Another potentially important application in drug discovery will be the use of small-molecule microarrays for the screening of protein inhibitors. Small molecules can be routinely synthesized in large numbers by parallel synthesis technologies and modified with functional groups for specific immobilization onto surfaces. Small-molecule microarrays are therefore of growing interest to the research community. Most of the groundbreaking work in this field has been performed by Schreiber and coworkers, who developed a variety of immobilization schemes for small molecules and demonstrated the use of small-molecule microarrays in elucidating pathways in glucose signaling and in discovering transcription factor inhibitors.

Additional recent innovations with respect to the immobilization of small molecules have been reported. The so-called Staudinger ligation has been

successfully used selectively to immobilize azide-functionalized molecules on phosphane-derivatized glass slides by forming an amide bond. Another strategy, which allows for the immobilization of non-functionalized molecules, including natural products, can also be applied for the production of small-molecule microarrays by using photoaffinity labeling. Although the small molecules are not immobilized in an oriented fashion, this technology is widely applicable and the random orientation enables one to display the molecules such that most, if not all, of the functional groups will be available on some proportion of the immobilized compounds.

A different but elegant approach has been to use a DNA array to derive information about protein–small-molecule interactions. To accomplish this, each of the small molecules is coupled to a unique PNA (peptide nucleic acid hybrid molecule) sequence and a fluorescent dye. A library of fluorescent small molecule-PNA hybrids are then mixed together and incubated with a target enzyme to allow binding to occur. Next, size-exclusion chromatography is used to separate the bound from the unbound library members. The bound members are then hybridized to an array of DNA sequences that hybridize to the different PNA tags, and a fluorescence scan of the array reveals which molecules have affinity for the target protein (Fig. 10).

The possibility of screening large libraries of small molecules with a variety of target proteins, under conditions of minimal sample consumption, could potentially have an important impact on the efficiency of the early steps in the drug discovery process.

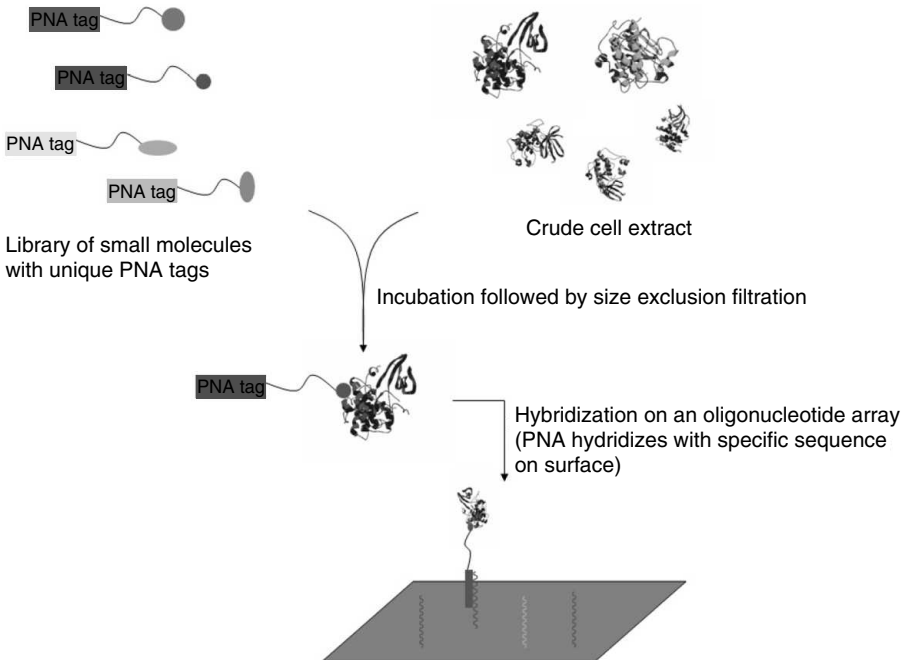

Fig. 10 Screening of protein interactions with PNA-encoded small molecule libraries as described by Winssinger and colleagues.

4.3 Alternative Technologies

The most important technology to date for the elucidation of protein–protein interactions are the two-hybrid systems. These are genetic-based *in vivo* screening systems that have been used extensively for the discovery of new interactions between proteins. The most widely used such system is in yeast and is based on the functional reconstitution of the transcriptional activator Gal4p. The interaction of two proteins is detected by fusing one protein to the DNA-binding domain of Gal4p and the other to the transcriptional activation domain. The interaction of the two proteins reconstitutes the activity of Gal4p, allowing for the transcription of reporter genes. Using the yeast two-hybrid system in large-scale screens, a detailed analysis of the whole ''interactome'' of yeast *S. cerevisiae* has already been performed. A disadvantage of the yeast-based system, however, is the fact that all interactions take place in the yeast nucleus, which is not an optimal environment for the proper folding of certain proteins, especially with respect to post-translational modifications. To solve this problem, other two-hybrid systems have been developed that allow for the interaction of two proteins in the cytoplasm of yeast or in mammalian cells.

Another *in vivo* screening system is based on reconstituting an enzyme from two polypeptide fragments by genetically fusing one protein of interest to one fragment and another protein to the other fragment. If the two proteins of interest interact, they bring together and reconstitute the genetically fragmented enzyme, making it active. The activity of the enzyme can then be followed by using a substrate that is converted into a fluorescent product, for example.

Many protein–protein interactions are not binary in nature but rather require the formation of multiprotein complexes. Different approaches have been developed to tackle this problem in which a large number of proteins are cloned into expression vectors and expressed with fusion tags, such that they can form protein complexes under physiological conditions. The tag can then be used to extract the protein complexes from cell lysates and then identify the proteins in these complexes by gel electrophoresis and mass spectrometry.

Each of these techniques has its advantages and disadvantages. The two-hybrid system, for example, can only elucidate binary interactions but is very efficient at detecting transient or weak interactions, in contrast to methods requiring the extraction of protein complexes. Only a combination of techniques can result in a more complete picture of protein interaction maps for complex biological systems. Protein microarrays are especially useful for the determination of protein interactions with other molecules such as DNA, RNA or carbohydrates. Even for the detection of protein–protein interactions, protein arrays can be *in vitro* alternatives to the cell-based two-hybrid system and may be useful where the latter is deficient, such as for identifying interactions involving secreted proteins.

5 Concluding Remarks

The emergence of proteomics has generated the need for new technologies that introduce parallel measurements and miniaturization into protein analysis. Protein expression profiling is particularly well suited to miniaturization, especially

for the analysis of soluble proteins such as growth factors and cytokines. Dozens of platforms that rely on different types of configurations and detection methods have been established. Both planar and suspension-based antibody arrays, using fluorescent sandwich pair antibodies for detection, have demonstrated that dozens of proteins can be analyzed quantitatively at picomolar concentrations in parallel. Further broadening the applications of this powerful technology will require the development of hundreds to thousands of new high quality antibodies. Multiplexed analysis of enzyme activity and protein interaction profiling is also technically well established and already has enabled important advances. For these technologies also, the rate-limiting step in developing further applications is the development of biological content, that is, collections of functional recombinant proteins. As such content becomes available, there is little doubt that protein microarrays will become a mainstream tool for biological research.

Keywords

***Ab Initio* Modeling**
The goal of *ab initio* modeling is to predict the structure of a protein from only its amino acid sequence.

Brownian Dynamics Simulation
Brownian dynamics simulations are related to molecular dynamics, but do not include the same amount of detail. Solvent in particular is normally represented as a continuous medium, which significantly decreases the complexity of the models and allows much longer simulations.

CASP, CAFASP, CAPRI
Critical Assessment of Structure Prediction (CASP), Critical Assessment of Fully Automated Structure Prediction (CAFASP), and Critical Assessment of PRedicted Interactions (CAPRI) are large-scale assessments in which hundreds of research groups submit their best structure predictions on the same set of targets, allowing a critical comparison between methods and an assessment of strengths and weaknesses of different methods and the field as a whole.

Docking
The term docking incorporates a group of methods for studying the interactions of small molecules and proteins. The process typically involves extensive searching of possible orientations of the small molecule in a binding site of the protein, and a scoring function that ranks different orientations by their likelihood of occurrence.

Fold Recognition
The goal of fold recognition is to predict which fold, out of ca. 1000 observed protein folds, a given sequence will adopt.

Homology Modeling
Predicting the three-dimensional structure of a protein on the basis of known structure of a related protein.

Molecular Dynamics Simulation
A computer simulation method in which the motions of all atoms in a molecular model, including water and ions are calculated over a period of up to a microsecond.

This computationally expensive method is one of the most detailed ways of studying the dynamics of macromolecules.

Molecular Graphics
Modern computer graphics are used to visualize molecular structures and models. The ability to highlight different features or properties in a three-dimensional model is a powerful way to explore molecules. Stereo hardware and immersive environments further enhance the usefulness of molecular graphics.

Poisson–Boltzmann Equation
The Poisson–Boltzmann equation describes electrostatic interactions between charges in a continuous medium (e.g. water) in the presence of salt. It can be solved numerically by several popular software packages to give insight into electrostatic interactions in proteins, between proteins and their substrates, between proteins and membranes, and in other systems. A common application is the calculation of pK_a-shifts for acidic and basic residues in proteins due to their environment.

Primary, Secondary, Tertiary, and Quaternary Protein Structure
The amino acid sequence of a protein is its primary structure. The α-helices, β-strands, and random coils are typical secondary structures that form between consecutive residues. They are defined by the hydrogen-bonding pattern and dihedral angles observed in the protein backbone. The tertiary structure of a protein describes the relative position of all the protein atoms in three-dimensional space. Elements of secondary structure that were far apart sequentially may now form higher order structures such as parallel or antiparallel β-sheets, or helix bundles. The quaternary structure describes how multiple proteins are arranged together in larger complexes.

QM/MM Simulation
A computer simulation method in which an important part of a system, such as the active site of an enzyme, is described by quantum mechanics, with the rest of the system described by molecular dynamics methods. The part of the system treated by QM includes explicit treatment of electrons.

Structural Genomics
A concerted effort to determine experimentally the high-resolution structure of all proteins in a genome, often with a focus on proteins that are predicted to be structurally different from all structures that are already in the database. This greatly increases the likelihood that a given sequence can be modeled using homology modeling.

Protein modeling consists of a broad range of computational techniques to understand the properties of proteins and has become an integral part of structural biology and drug design. Modeling can be used to predict the secondary structure or fold of a protein on the basis of its sequence alone, to predict the three-dimensional structure of a protein on the basis of knowledge of the structure of a related protein,

to design new proteins, and to predict properties that depend on the experimentally determined three-dimensional structure of a protein. Examples of such properties include drug binding, protein–protein interactions, and interactions with elements in a protein's environment, including ions, lipids, carbohydrates, and nucleic acids. Conformational changes in proteins can be investigated by molecular dynamics simulations to provide detailed insight into the dynamics of proteins, a crucial aspect of protein function. In recent developments, quantum mechanical calculations are used more and more frequently to study reactions in proteins. With the ever-increasing power of computers, increasingly detailed aspects of protein function can now be investigated by modeling methods, at a scale and level of detail that is often very difficult or impossible to achieve by experimental methods.

In this chapter, the main principles and techniques involved in protein modeling are introduced. A few examples from the literature will highlight how protein modeling can be used in complement with other methods.

1 Introduction

1.1 Primary, Secondary, Tertiary, and Quaternary Structure of Proteins

Proteins are structured at different levels. The primary structure of a protein is its amino acid sequence, encoded by DNA. All proteins are constructed from about 20 common amino acids as well as some amino acids that are formed through chemical modification. The secondary structure of a protein is a sequence of common structural, three-dimensional elements or building blocks. These secondary structure elements include α-helices and β-strands as best-known elements, but there are many other building blocks. The tertiary structure of a protein is its three-dimensional structure in space, which can be thought of as placing the secondary structure elements together in space. The quaternary structure of a protein describes how multiple proteins interact through noncovalent forces to form larger protein complexes. An example of the different levels of structure is shown in Fig. 1, based on the protein barstar. It is shown in a protein complex with barnase to illustrate quaternary structure. The minimal requirement for modeling proteins is knowledge of the primary structure. Since the primary sequence is one of the main results of genome sequencing, this is a very modest requirement. As more experimental structural information becomes available, modeling typically becomes more accurate by using that experimental information to identify plausible models. Any experimental information that puts limitations on possible models is useful.

1.2 Relationship between Structure and Function

A basic assumption in protein science is that the function of a protein follows from its structure. Yet, proteins with very similar three-dimensional structure can have very different functions, so

Fig. 1 (a) The primary sequence of the protein barstar in FASTA format. (b) The secondary structure of the first 60 residues of barstar, colored purple for helices, and yellow for β-strands. All are shown in ribbon format. (c) The complete tertiary structure of barstar in cartoon format. The helices are now bundled together, and the β-strands have formed a three-stranded parallel β-sheet. (d) Example of quaternary structure: the barnase/barstar complex. Barstar (red) and barnase (blue) area shown in ribbon and spacefilling formats. Images created with VMD using the PDB entry 1B2U. (See color plate p. xxx.)

precise details of the three-dimensional (tertiary/quaternary) structure are very important. Nonetheless, there is a large amount of information contained in the primary and secondary structure of a protein. Indeed, nature in most cases only seems to need the primary sequence, but computational methods are not yet able to reliably predict the three-dimensional structure of proteins based on primary sequence alone. At the current state of the art, a primary sequence is useful to compare proteins of known function with a similar sequence and sometimes allows assignment of a tentative function. Knowing the secondary structure of a protein significantly narrows down the range of possible three-dimensional structures. It allows a comparison with databases of the secondary sequence of known proteins, which often makes it possible to recognize the three-dimensional fold of a protein on the basis of the secondary structure alone. Interestingly, although in principle the number of possible three-dimensional structures is practically infinite, only about 1000 different ''folds'' seem to occur in nature. This is particularly useful for whole-genome studies: if we can use the primary sequence and predictions or knowledge of the secondary structure, chances are reasonable that the fold of the protein can be recognized. This is a

constructive step toward attaining a three-dimensional structure.

The three-dimensional structure of a protein is the most useful level for molecular modeling. At this level, the interactions between small molecules (drugs, substrate) and an enzyme, permeation properties of ion channels and transporters, activation of receptors by ligand binding, and chemical reactions in enzymes and other processes that require a very detailed knowledge of atomic structure to understand them can be studied. This level is also required to study interactions between protein subunits or for protein–protein or protein–peptide interactions. In practice, the best way to obtain knowledge of the three-dimensional structure is from experimental structure determination, but prediction methods primarily based on homology modeling (see Sect. 2) are increasingly becoming accurate enough to provide useful starting points for further computational studies.

1.3 Experimental Structure Determination Methods

There are several experimental methods to determine the structure of proteins. The primary structure is determined by sequencing, either of the protein itself or of the DNA that encodes the protein. The secondary structure can be measured by spectroscopic methods, which usually determine a percentage of various secondary structure elements. Common techniques to do this are CD (circular dichroism) spectroscopy, IR (infrared) spectroscopy, and NMR (nuclear magnetic resonance) spectroscopy.

As a basis for detailed modeling problems, high-resolution 3-dimensional structures are typically required. The two main methods to experimentally determine 3D structures are X-ray crystallography and nuclear magnetic resonance. Electron microscopy is a third method that has been used to solve the structure of several membrane proteins. Crystallography is a very powerful method that can be used on proteins and protein complexes of any size. The main limitation of the method is that a protein must form regular crystals. Not all proteins do this (especially membrane proteins), and sometimes crystallization forces proteins in structures that are probably not physiologically relevant. NMR experiments can determine the structure of a protein in solution, which is usually a more realistic environment. The main limitations of solution NMR are that it is difficult to apply the method in practice to proteins that are larger than ca. 40 kDa, and that it is usually considerably more labor intensive to determine a structure by NMR compared to crystallography. These limitations have spurred the development of new methods that are catered to work with larger proteins, and to make the process of structure calculation from a measured spectrum more automated. Solid-state protein NMR is a relatively new field that can be used to determine the structure of proteins in ordered systems, such as membranes. Electron microscopy as a method to determine 3-D structures has been mainly used for membrane proteins, which are especially difficult to crystallize for X-ray crystallography. The method is very labor intensive. It does have a significant strength for very large complexes, where the overall arrangement of large subunits can be seen at low resolution. The details of the structure can then be added from crystal structures of individual proteins that make up the complex.

1.4 Role of Modeling

Modeling has many potential uses, at different levels of protein structure. Protein modeling is such a broad field it may be beneficial to distinguish two separate general goals.

One set of goals consists of predicting aspects of the structure of a protein based on less detailed information. If only the primary structure (the sequence) of a protein is known, we can try to predict the secondary structure with reasonable accuracy, often in the 75 to 85% range. On the basis of the degree of hydrophobicity of predicted helices, it is usually also possible to predict transmembrane segments, identifying a protein as a membrane protein, with reasonable accuracy. The secondary structure can be useful to predict the general fold of a protein, which may make it possible to assign a tentative function to the protein. Predicting the tertiary structure directly from the sequence is a very difficult problem with a low success rate. If a high-resolution structure of a related protein is known, then homology modeling can be used to provide a good model of the target protein. In principle, such modeling efforts make it possible to circumvent experimental structure determination. One major goal of protein structure research at the moment is to improve all steps in the process that leads to an accurate three-dimensional model, both by improving *ab initio* prediction methods and by experimentally determining enough protein structure that homology modeling becomes feasible for most proteins in the genome – ideally, one could then obtain structural models for all proteins in an organism directly from its genome sequence. As the number of structures solved experimentally increases, the algorithms to detect homology between remotely related proteins and built homology models will improve, making this goal increasingly feasible.

A second set of goals starts from an experimentally determined high-resolution structure (or a very high-quality homology model) and uses physics-based methods to model aspects of a protein that cannot be easily determined experimentally. This type of approach could include electrostatics calculations to understand how proteins interact with substrates or other proteins, docking calculations to understand differences in binding constants and design new inhibitors for enzymes, or detailed molecular dynamics simulations to investigate the dynamics of proteins. This type of goal usually involves much more biochemical knowledge of the protein and is often centered on very specific questions: why does mutating residue x to alanine change the binding affinity of a particular drug by a factor of 1000? Why is this ion channel selective for potassium over sodium, even though the only difference between potassium and sodium superficially is a small difference in radius?

In the following sections we consider each set of goals in more detail and give specific examples.

2 Structure Prediction Methods

2.1 The Protein-folding Problem

One of the most challenging problems in biophysics is to understand how it is possible that proteins fold rapidly (microseconds to seconds) into a well-defined structure when based on their primary sequence alone, a practically infinite number

of structures is possible. Levinthal showed that folding on a realistic timescale could therefore not occur through a systematic search of all possible conformations (Levinthal's paradox). Major research efforts are devoted to understanding protein folding, with a significant focus on the physics of simplified models. Clearly, if it is possible to fold a protein *in vivo* from the sequence only, then with a proper understanding of the laws governing protein folding, we should be able to predict any protein structure computationally. This is still a lofty goal, but in the past years major progress has been made in improving prediction methods at all levels of structure. This progress has been documented strikingly in the proceedings of the semiannual CASP competition (Critical Assessment of Structure Prediction).

CASP is an interesting and exciting venture involving a large scientific community. Its main goal is to obtain an in-depth and objective assessment of our current abilities and inabilities in the area of protein structure prediction (http://predictioncenter.llnl.gov). It involves a neutral organizing committee that collects unpublished, but already solved protein structures from experimental structure determination groups. Specific information, such as the protein's primary sequence, is published on a Web site, and modeling groups can attempt to predict the structures. A panel of assessors judges the predictions against the real structures, and at the CASP scientific meeting the results are discussed, areas of progress and areas of problems are identified, and the progress and directions of the field as a whole are examined. This procedure makes CASP a very fair way of establishing the merits of particular methods and of identifying where future efforts can be most productively focused. CASP6 was held in December 2004 in Italy. In the last few years, CASP has begun to introduce automated prediction software as a separate exercise (CAFASP – Critical Assessment of Fully Automated Structure Prediction). The process has also been adapted to predicting protein–protein interactions (CAPRI – Critical Assessment of PRediction of Interactions), which saw its first edition in 2001. More details about CAPRI can be found at http://capri.ebi.ac.uk. These competitions give a novice in the field of structure prediction an excellent starting point to compare the many protein modeling programs and help a user to decide which program would work best with their requirements. Despite differences in the performance of these programs, many of them draw from the same fundamental approaches to protein structure prediction. The three main approaches are discussed in the following.

2.2 *De Novo/Ab Initio* Methods

De novo methods are a general designation for methods that predict the structure of a protein on the basis of the primary sequence alone. The ideal method to do this would be based on simple physical laws only. Although this would be a true *de novo* method, it is exceedingly difficult and has only been modestly successful for peptides and small proteins. The difficulty is the extremely large number of possible conformations for a polypeptide chain; predicting the structure of a protein from the sequence only would indeed be equivalent to solving the protein-folding problem. In practice, *de novo* methods incorporate a variety of information derived from a database

of existing structures. This can be very direct information, such as taking the conformation of a loop with the same sequence directly from the database, or less direct, such as through heuristical rules derived from statistical analysis of all known protein structures.

2.3 Fold Recognition Methods

Fold recognition methods attempt to identify structures within a new protein (the query) by comparing its sequence to proteins with known structure (the template). This can be called the *inverse folding problem*, since the goal is to find probable folds that might fit the sequence instead of trying to determine how the sequence will fold.

There are two broad approaches to fold recognition methods. The first approach is sequence-based. It relies on finding homologous sequences and then assumes that strong sequence similarity equates to strong structure and function similarity. While this may seem straightforward, current algorithms may not be sensitive enough to recognize distant homologs, and therefore the ''correct'' template might be missed; as well, mutations between these sequences, including gaps and insertions, sometimes make it difficult to identify the correct sequence alignment. It can be misleading to rely on the sequence alignment alone for fold recognition. It is possible to identify proteins with some sequence identity that do not have any structural or functional similarity to the query, and so, blind sequence alignments may not yield a successful prediction. Classifying protein sequences into families, and then identifying the patterns within the family such as strongly conserved residues (which might be important to function) and the pattern of mutations (For example, is a hydrophobic residue always replaced by another hydrophobic residue? That is an acceptable mutation.) can improve the confidence of your alignment. PSI-BLAST is one of the most popular homology recognition algorithms, although there are a number of others that also perform well.

The second approach to fold recognition is structure-based. ''Threading'' is a popular term for this approach, which evokes the image of the thread-like primary sequence being ''threaded'' through the three-dimensional structure of template proteins. Finding the optimal fit of the sequence with each framework is a complex process, particularly if there are gaps and deletions among the sequences of the two proteins. It is very common to use sequence-based methods in conjunction with threading to identify the best matches. Each iteration of the threading process is scored and this score is used to determine the best matches. Following Anfinsen's hypothesis that the native state of the protein is the lowest energy structure, the evaluated energy of the query's fit to the template is a strong predictor of which models are ''good'' within an experiment. There are a number of threading algorithms available, varying in their choice of protein model (backbone atoms vs just α-carbon atoms, side chains vs interaction sites), their method of alignment, as well as their method of evaluating the energy of the proposed structure, just to name a few differences.

When embarking on a fold recognition study, the state of the art of current fold recognition methods can be judged from results of the previously discussed CASP competition, and also of the Live Bench Project. Unlike CASP, the targets in this exercise are recently deposited structures

from the Protein Data Bank. All of the methods assessed are fully automated. An expanding number of fold recognition servers (as well as metapredictors and sequence comparison servers) participate in this weekly assessment exercise, and the most current results can be found on the Web at http://bioinfo.pl/livebench/. It is important to recognize that fold recognition methods are mostly knowledge-based. They are making predictions based only on what is already known. This means that it is impossible to identify any novel folds. Novel fold prediction would fall into the category of an *ab initio* method, where the predictions are based primarily on physical principles.

2.4 Homology Modeling

Homology modeling is the only generally useful method to predict the total three-dimensional structure of a protein. It is based on the observation that the structure of a protein during evolution is much more conserved than the sequence, so that sequences that differ somewhat are still likely to have the same structure. ''Somewhat'' can be quantified on the basis of the database of known structures: if two proteins with more than ca. 50 residues have a sequence identity of ca. 20 to 30%, they will likely have the same structure. Thus, homology modeling can be used if there is a protein with a known structure (the template) that is sufficiently homologous to the protein whose structure we want to model (the target). In practice, homology modeling follows a series of steps, each of which involve choices by the modeler, or an automated computer server. Following Krieger et al., homology modeling can be thought of as involving seven steps:

1. Template recognition and initial alignment
2. Alignment correction
3. Backbone generation
4. Loop modeling
5. Side-chain modeling
6. Model optimization
7. Model validation

The overall strategy is to begin with aligning the sequence of the target with that of the template, to build the overall chain structure of the target, and then to consider ''details.'' The accuracy of this alignment is the most important determinant of the accuracy of the model. Step 2 is a manual correction of the alignment if there is a compelling reason to do so. For example, in potassium channels there is a nearly universally conserved motif TVGYG that is likely to be aligned even if multiple-sequence alignment algorithms offer alternative alignments. The backbone of the target is typically initially copied from the template, followed by algorithms that allow some flexible adjustments where necessary. The major problems in homology modeling typically involve insertions that are not present in the template. In potassium channels, the loops between transmembrane helices can be very different between channels, even if the transmembrane segments are very similar. Similarly, the loops connecting the transmembrane helices in G-protein coupled receptors convey much of the specificity of different receptors, but this most interesting part generally cannot be modeled by homology modeling. Thus, being able to model loops for the targets that are missing in the template is an important step, and a significant research focus. Once the backbone has been optimized as much as possible, side chains can be modeled and the model tested against experimental

information. In many cases, steps have to be repeated.

It is now usually fairly easy to generate homology models, provided a suitable template is available. Commonly used programs include Modeller and WhatIf, as well as automated Web servers such as SwissModel. The key measure of success for homology models is their experimental validation, but less than perfect models can be very useful in interpreting experiments and guiding the design of new experiments.

3 Structure-based Modeling

3.1 Molecular Graphics-based Methods

Over the past 5 to 10 years, the personal computer has begun to replace the large supercomputers and dedicated workstations once needed to use molecular visualization tools. Today, a number of molecular graphics programs are available for use on personal computers, often as freeware. Any program with basic rendering capabilities can be a valuable tool to study a particular protein. A variety of representations, illustrated in Fig. 2 for the protein barnase, can help the modeler understand the link between the protein's structure and its function. By manipulating colors and representations, one can interrogate the structure to see where conserved residues/sequences are in the protein's structure, look at the overall surface of the protein as a guide to potential protein–protein interactions, and look for cavities that might be ligand-docking sites, just to name a few examples. In this section, we aim to point out a few commonly used programs for protein

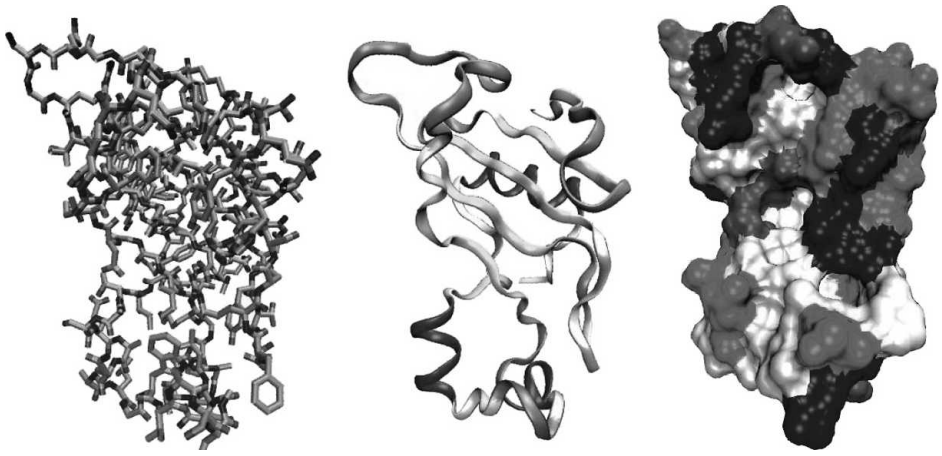

Fig. 2 Barnase rendered in three formats: (a) colored by atom-type (carbon – blue, nitrogen – navy blue, oxygen – red); (b) colored by secondary structure features in ribbon format, where β-sheets are colored yellow, helices are colored purple, and turns and random coil features are colored blue and white; (c) rendered in surface format, colored by residue type, where charged residues are colored red or blue, polar residues are green, and nonpolar residues are white. All figures are rendered with the same view of the protein, looking into the barstar binding pocket. All figures were rendered with VMD. (See color plate p. xxxii.)

modeling. Besides those mentioned here, a few more are described by Tate, and even more are listed on the PDB Web site (http://www.rcsb.org/pdb/software-list.html).

Rasmol is one of the most widely used programs for molecular visualization. Besides the basic options in which the display of the protein can be altered from sticks to spacefilling to ribbon format, and so on, there are a variety of tools that can be used through the command line interface. Examples include selection of specific residues of the protein, measuring distances, and highlighting parts of the protein within a certain radius. Rasmol can be used to probe all of the information contained in a ''.pdb file,'' but it has few tools to alter that information. With Swiss-PDB Viewer, protein structures can be manipulated in a number of ways. Residues can be ''mutated,'' and dihedral angles can be modified. This program provides a graphical interface within which several protein structures can be analyzed and manipulated at the same time. Moreover, Swiss-PdbViewer is tightly linked to SwissModel, an automated homology-modeling server. Working with these two programs greatly reduces the amount of work necessary to generate models, as it is possible to thread a protein primary sequence onto a three-dimensional template and get an immediate feedback of how well the threaded protein will be accepted by the reference structure before submitting a request to build missing loops and refine side-chain packing.

VMD is another very powerful visualization program, which can also be used to view trajectories from molecular dynamics simulations. It has a broad range of representations for proteins, including molecular surfaces, electrostatic potential maps, and crystal information. Other useful programs are PyMol and MolMol.

3.2 Poisson–Boltzmann/Electrostatics Calculations

Poisson–Boltzmann theory (PB) has become an important tool for studying biomolecular systems. This type of calculation provides a view of a protein in terms of regions of positive or negative potential. PB calculations are useful for identifying interaction sites on proteins with charged ligands or other proteins. They can also be used for calculating amino acid pK_as in different environments, such as in enzyme active sites where catalytic residues often have large pK_a shifts due to their local environment. PB calculations also provide a basis for Brownian dynamics simulations (see Sect. 4).

PB is based on the Poisson equation, which describes electrostatic interactions in general, but includes implicitly the presence of ions in solution. It is assumed that at equilibrium, the distribution of mobile ions in the system can be approximated by a continuous charge density $\rho_{eq}(\mathbf{r})$, determined by the Boltzmann factor:

$$\rho_{eq}(\mathbf{r}) = \sum_i z_i e n_{0i} \exp\left[-\frac{z_i e \phi(\mathbf{r})}{kT}\right]$$

where i is an ionic species, z_i the charge of ion species i, n_{0i} a reference number density for species i, e is the unit charge, and $\rho(\mathbf{r})$ and $\phi(\mathbf{r})$ are the local equilibrium charge density and the average electrostatic potential, respectively. The electrostatic potential $\phi(\mathbf{r})$ is the solution of Poisson's equation:

$$\varepsilon_0 \nabla.[\varepsilon(\mathbf{r})\nabla\phi(\mathbf{r})] = -\rho_{eq}(\mathbf{r}) - \rho_{ex}(\mathbf{r})$$

Assuming a 1:1 electrolyte, these two equations can be combined to give:

$$\varepsilon_0 \nabla.[\varepsilon(\mathbf{r})\nabla\phi(\mathbf{r})] = 2en_0 \times \sinh\left[\frac{e\phi(\mathbf{r})}{kT}\right] - \rho_{ex}(\mathbf{r})$$

Here the mobile charges represented by ρ_{eq} are in equilibrium, and the fixed charges on the protein or membrane are represented by ρ_{ex}. This is the full nonlinear Poisson–Boltzmann equation, which can be solved numerically. It can be linearized by expanding sinh and retaining only the leading term. When there are no fixed charges and assuming a spatially homogeneous dielectric, this simplifies to:

$$\nabla^2\phi = \kappa^2\phi$$

with κ^{-1} is Debye screening length, given by:

$$\kappa^{-1} = \sqrt{\frac{\varepsilon_0\varepsilon kT}{2e^2n_0}}$$

The Debye screening length $\kappa^{-1} = 8$ Å for 150 mM salt at 298 K in water with a dielectric constant of 80. The screening of a central charge in bulk solution is about 80% at $r = 3\kappa^{-1}$, or ca. 25 Å. This distance decreases to about 9 Å for 1 M salt solution.

The Poisson–Boltzmann equation, either in its linear or nonlinear form, can be solved for macromolecules by a number of commonly used programs, including DelPhi, UHBD, and APBS.

3.3 Ligand Docking

The binding of small molecules to proteins is a key determinant of many biological processes. The ligand-docking problem is the challenge to predict where, in what orientation, and with what affinity a small molecule binds to a binding site in a protein. In the ultimate state of the art, one would like to predict all three with high accuracy, for a high computational cost if necessary. In addition, we also need methods that allow rapid (computationally inexpensive) screening of a library of millions of compounds to search for drug leads that may interact favorably with potential drug targets. Broadly speaking, ligand docking can be approached from two angles. In the first approach, compounds of known structure are docked into the active site of a protein of interest, and some form of scoring function is a measure of how likely the compound will bind tightly to the protein. In the second approach, starting from the known structure of the protein, a molecule can be designed by fitting functional groups in the active site to optimize the interactions with the protein target. The resulting "computational" molecule can then be synthesized and tested. Several classes of scoring functions exist. One class is based on a combination of interaction energies, with terms that are similar to the potential function used in molecular dynamics simulations. Simpler functions based on, for example, the number of hydrogen bonds or penalties for steric clashes are also useful and can be computationally faster. A second class tries to directly calculate the free energy of binding using a parameterized function or an approximate description of the free energy of binding derived from a potential function. A third class uses statistical information about similar molecules and general features of the binding site to rank ligand–protein complexes. At the moment a combination of methods seems to give the best results, but to our knowledge there is no consensus on which method is the best in any given case.

3.4 Protein–Protein Interactions

Protein–protein interactions are emerging as one of the most important themes in biochemistry. Some interactions are sufficiently stable that a complete complex can be crystallized, but this is relatively rare. More often, proteins interact transiently with other proteins at some point in their lives, often in critical processes such as signaling. The protein database contains mainly single proteins, because to crystallize them they are normally purified to a high degree, thus disrupting all but the strongest noncovalent interactions.

The general goal of protein–protein docking could be described as predicting correctly the structure of a protein–protein complex, given only the structures of the two independent proteins. This assumes that these structures are already known. Whether the proteins are allowed to change their structure somewhat upon binding, which seems realistic, is an additional complexity. There are many approaches in the literature, with two common themes. First, there is a remarkable degree of surface complementarity in most stable complexes. This suggests that it should be possible to draw a molecular surface on both proteins (e.g. see Fig. 1d) and search for all possible relative orientations of the two proteins for the most favorable orientation. This type of search is expensive, and the challenge is to identify the most favorable orientation among many possible orientations. Usually, some form of energy function is used, which gives more favorable values for orientations that optimize interactions such as hydrogen bonding, burying of hydrophobic exposed area, and matching up complementary electrostatic potentials on the surfaces of the proteins that form the complex. A second approach combines experimental data with energy functions to guide the two proteins to a solution that is compatible with experimental data. A recent successful example of this approach is HADDOCK, which combines a molecular mechanics energy function, a simplified form of dynamics to enable flexibility of parts of the interface, and incorporation of ''ambiguous interaction restraints.'' These are ''soft'' restraints that, by themselves, are insufficient to guide docking but combine to yield more reliable solutions than energy functions alone, provided there is experimental information that can be used as restraints. As mentioned above, progress in the area of protein–protein docking is monitored in the CAPRI challenge (http://capri.ebi.ac.uk).

4 Simulations of Protein Dynamics

Three common simulation methods used to study protein dynamics are explained here.

4.1 Molecular Dynamics Simulation

The most common atomistic simulation technique is molecular dynamics (MD). In MD simulations, the interactions between all atoms in the system are described by empirical potentials. An example of a frequently used potential function is:

$$V(\mathbf{r}^N) = \sum_{\text{bonds}} \frac{k_i}{2}(l_i - l_{i,0})^2 + \sum_{\text{angles}} \frac{k_i}{2}(\theta_i - \theta_{i,0})^2 + \sum_{\text{torsions}} \frac{V_n}{2}(1 + \cos(n\omega - \gamma))$$

$$+\sum_{i=1}^{N}\sum_{j=i+1}^{N}\left(4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12}-\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right]+\frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}}\right)$$

This potential function contains harmonic terms for bonds and angles, a cosine expansion for torsion angles, and Lennard–Jones and Coulomb interactions for nonbonded interactions. The constants k_i are harmonic force constants, l_i, is the current bond length, $l_{i,0}$ the reference bond length, θ_i the current angle, $\theta_{i,0}$ the reference angle, V_n, n and γ are the barrier height, multiplicity, and off-set from the origin for the cosine function used to describe dihedral angles (rotations around a central bond), ε and σ are Lennard–Jones parameters (a different pair for each possible combination of two different atom types), q_i and q_j are (partial) atomic charges, and r_{ij} is the distance between two atoms, and ε_0 (different than ε in the Lennard–Jones potential) is the dielectric constant of the medium. Using this potential function, the forces (the derivative of the potential with respect to position) on all atoms in the system of interest are calculated and used to solve classical equations of motions to generate a trajectory of all atoms in time. An example of a system studied with MD is shown in Fig. 3: a simulation snapshot of the ABC transporter BtuCD in a realistic environment consisting of lipids, water, and ions.

The primary result of the simulation is a trajectory of all atoms in time, from which specific details of the system can be analyzed. This is an exciting idea, because atoms can be followed as they move in real time on a timescale of up to ca. 100 ns, although longer simulations have also been reported. In principle, any properties that depend on coordinates, velocities, or forces can be calculated, given sufficient simulation time. No assumptions are required about the nature of the solvent, there is no need to choose dielectric boundaries because all atoms are explicitly present, and in principle all interactions (water–ions,

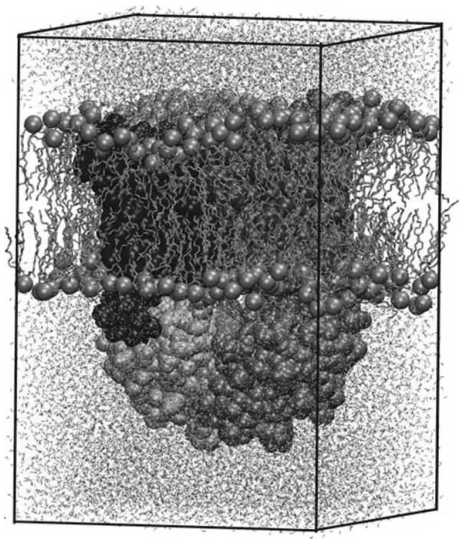

Fig. 3 An orthographic view of the periodic box for the ATP-bound BtuCD simulation, showing water (red and white), lipid with phosphorus atoms enlarged, and the protein. The transporter consists of two transmembrane domains (blue and purple) and two nucleotide binding domains (orange and ochre). The two docked MgATP molecules are partially visible (green and red). Figure courtesy of E. Oloo. See Oloo, E.O., Tieleman, D.P. (2004) Conformational transitions induced by the binding of MgATP to the vitamin B_{12} ABC-transporter BtuCD, *J. Biol. Chem.* **279**, 45013–45019 for more details. Rendered with VMD. (See color plate p. xxx.)

water–protein, water–lipid, lipid–protein etc.) are incorporated.

The main limitations of MD are its computational cost, the limited time and length scale that can be treated in a simulation, and technical limitations such as the accuracy of current empirical force fields.

4.2 Free-energy Calculations

Several useful extensions of the basic simulation method make it possible to calculate free-energy differences from simulations. If a reaction coordinate can be identified, processes that are orders of magnitude slower can be studied than would be possible by direct simulation. Such a reaction coordinate could be a concerted conformational change, or a pathway for ion permeation in ion channels. In umbrella sampling, a biasing potential is used to restrict a simulated system to sample phase space within a specified region (called a *window*). By placing windows along the reaction coordinate, one can generate a free-energy profile (also called *potential of mean force*), which will quantitatively describe why one region of space is more favorable than another.

Relative free energies of different side-chain mutations in a protein can be studied using free-energy perturbation by slowly changing one side chain into another within the computer (also known as computational alchemy). This makes it possible to investigate in the computer the effect of mutations on the stability of a protein or on, for example, the binding affinity of a ligand. The theory behind this kind of calculations is well developed and the algorithms have been implemented in many molecular dynamics software packages.

4.3 Brownian Dynamics Calculations

In Brownian dynamics (BD) simulations, the trajectories of individual particles (ions, molecules) are calculated using the Langevin equation:

$$m_\mathrm{i}\frac{\mathrm{d}\mathbf{v}_\mathrm{i}}{\mathrm{d}t} = -\gamma_\mathrm{i}\mathbf{v}_\mathrm{i} + \mathbf{F}_\mathrm{R} + \mathbf{F}_\mathrm{i}$$

where m_i, *and* $\mathbf{v}_\mathrm{i}$ are the mass and velocity of atom i. Water molecules are not included explicitly, but are present implicitly in the form of a friction coefficient $\gamma = \mathrm{kT}/D_\mathrm{i}m_\mathrm{i}$ (where k is the Boltzmann constant, T is temperature, and D is the diffusion coefficient) and a stochastic force $\mathbf{F}_\mathrm{R}$ arising from random collisions of water molecules with ions, obeying the fluctuation-dissipation theorem. $\mathbf{F}_\mathrm{i}$ is the force due to other particles in the system as well as external sources, such as an applied electric field. When the friction is large and the motions are overdamped, the inertial term $m_\mathrm{i}\mathrm{d}\mathbf{v}/\mathrm{d}t$ may be neglected, and the simplified form

$$\mathbf{v}_\mathrm{i} = \frac{D_\mathrm{i}}{kT}\mathbf{F}_\mathrm{i} + \mathbf{F}_\mathrm{R}$$

may be used. This is the approximation made in Brownian dynamics.

BD simulations require only a few input parameters: in its simplest form, only the diffusion coefficients of the different species of ions and the charge on the ions are needed. However, the model can be refined. To study a protein such as an ion channel, the residues of the protein can be modeled as a set of partial charges, and some form of interaction potential between the mobile ions and the protein must be specified (as seen earlier).

The result of BD simulations is a large set of trajectories for diffusion particles such as ions, proteins, or ligands. By

averaging over these trajectories macroscopic properties such as the conductance of ion channels or association rate of protein–protein or protein–ligand encounters can be calculated. In addition, the simulations yield molecular details of the paths through space for the diffusing particles.

Although Brownian dynamics simulations are conceptually simple, replacing solvent by a continuum description and ignoring internal conformational changes in proteins are significant assumptions that require careful consideration. When BD simulations are valid, they are a very powerful method to study biological processes on a timescale that is much longer than can be reached by MD.

5 Example Applications

The literature is now very extensive, and hundreds of papers are published that are based on each of the methods described above. For illustration purposes, we give a few examples of biochemical problems that have been addressed by modeling and simulation methods.

5.1 Acetylcholinesterase

Acetylcholinesterase (AChE) is an extremely fast enzyme that hydrolyzes the neurotransmitter acetylcholine to terminate signaling in cholinergic synapses. It has been studied in great detail by a number of computational methods, including molecular dynamics simulations, continuum electrostatics calculations and Brownian dynamics simulations.

One of the first puzzles posed by the crystal structure of AChE is the question of how the substrate acetylcholine gains access to the active site, since in the crystal structure there is no unobstructed pathway to the active site. This original observation for AChE from the fish *Torpedo californica* has subsequently been reiterated in mouse and human AChE. Simulations have shown how breathing motions in the enzyme facilitate the displacement of substrate from the surface of the enzyme to the buried active site. These motions appear quite complex and spatially extensive, which suggests possible modes of regulation of the activity of the enzyme. Such a mechanism has been observed in other proteins, including hemoglobin and myoglobin, but the fast reaction rates of AChE are hard to reconcile with major structural rearrangements. MD simulations suggest that the primary point of access opens and closes on a timescale that is fast enough not to slow down the entrance of the substrate substantially. Interestingly, the protein appears to have several secondary channels that allow water to enter and leave the active site as the substrate enters.

The reaction rate of AChE is limited by the diffusion of the neurotransmitter acetylcholine. Brownian dynamics are a suitable method to study encounters of acetylcholine with AChE. The acetylcholine diffuses under the influence of intermolecular interactions between acetylcholine and the protein and a random force. The net effect is that the protein ''guides'' the acetylcholine to its active site through an electrostatic mechanism that enhances the rate of finding acetylcholine beyond the pure diffusional limit. A similar mechanism has since been identified for several fast-reacting proteins.

AChE is the target of the neurotoxin fasciculin, a peptide. Brownian dynamics of the peptide and AChE give insight into

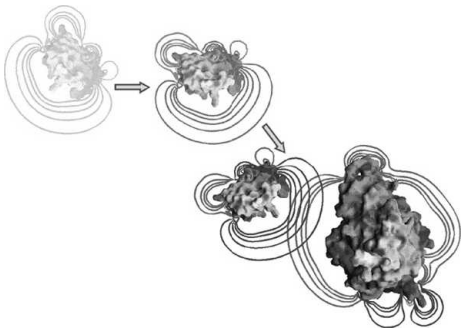

Fig. 4 Schematic illustration of the association of fasciculin (on the left) with acetylcholinesterase. Blue and red contour lines indicate regions of positive and negative electrostatic potential, respectively. Figure courtesy of D. Sept and A. Elcock. See Elcock, A.H., Gabdoulline, R.R., Wade, R.C., McCammon, J.A. (1999) Computer simulation of protein-protein association kinetics: acetylcholinesterase-fasciculin, *J. Mol. Biol.* **291**, 149–162 for more details. (See color plate p. xxiv.)

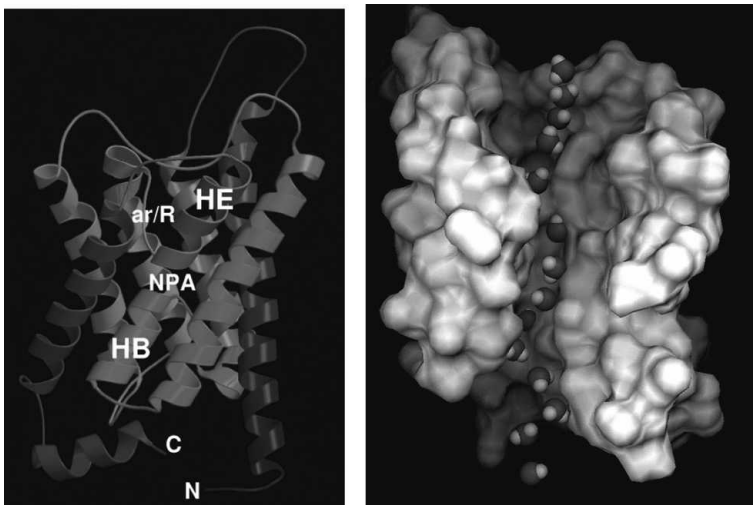
the binding kinetics of fasciculin and the structure of the resulting complex. In a series of Brownian dynamics simulations, Elcock et al. investigated the effect of mutations in the protein on association rate constants. The electrostatic interaction between AChE and fasciculin that promotes association is illustrated in Fig. 4. In its simplest form, the Brownian dynamics simulations reproduced the correct order of rate constants for different mutants, although the absolute values were too large by about a factor of 30. In a more accurate treatment of the continuum electrostatics problem, this discrepancy can be reduced greatly. Interestingly, these calculations make it possible to distinguish kinetic and thermodynamic effects, and suggest that for the case of fasciculin-AChE-binding mutations can separately affect the rate of association and the binding constant.

5.2
Water Transport Through Aquaporins

Aquaporins are ubiquitous membrane proteins that aid in the maintenance of crucial osmotic balance in cells, on whose discovery the Nobel Prize in chemistry was awarded in 2003. The road to high-resolution structures of these proteins, and to understanding with atomic detail how they function, is a nice example of the link between experiment, modeling, and simulations.

In early 2000, De Groot and coworkers used 4.5-Å resolution data, insufficient to identify the fold of the protein directly, to predict the fold of aquaporin based on the constraints of helix packing, atomic force microscopy data, and primary sequence. From 1440 possible folds, they were able to identify a maximum of 8 possible folds. Later that year, a 3.8-Å resolution structure of aquaporin from cryoelectron microscopy became available, as well as a 2.2-Å X-ray crystal structure for a homolog of aquaporin, GlpF, the glycerol transport facilitator. The fold of aquaporin is illustrated in Fig. 5(a). It has six transmembrane helices in an ''hourglass'' arrangement. The protein pore is shaped by two reentrant loops on either side of the membrane that have a conserved coil–NPA–helix motif, in which the Asn-Pro-Ala (NPA) residues of these loops meet in the middle of the channel. The partial helices of this motif are labeled HB and HE. The aromatic rich constriction region (ar/R), labeled in Fig. 5(a), is suspected of contributing to aquaporin's highly specific behavior.

Direct simulation of the AQP structure obtained from cryoelectron microscopy



(a) (b)

Fig. 5 (a) Ribbon diagram of the aquaporin monomer and (b) spacefilling representation illustrating a water file through the channel pore. (a) Starting at the N-terminus of the monomer, there are two transmembrane helices, followed by the coil–NPA–helix motif. A third transmembrane helix completes the first half of the protein. The second half of the monomer has two transmembrane helices, followed by the coil–NPA–helix motif, followed by another transmembrane helix. (b) The path of the water channel is through the core of the protein, following the path of the coil motifs, which meet at the NPA signature. This is more clearly illustrated in 5(b). The protein is rendered as a molecular surface in white, with the front surface of the protein cut away so that we can clearly see the pore in the middle of the protein. Surfaces colored yellow are those that interact most strongly with passing water molecules. The waterfile displayed is an overlay of a number of snapshots from the 10 ns simulation. The dipole inversion of water at the NPA motif is clearly illustrated here. Figure courtesy of B. de Groot. See De Groot, B.L., Grubmuller, H. (2001) Water permeation across biological membranes: mechanism and dynamics of aquaporin-1 and GlpF, *Science* **294**, 2353–2357. De Groot, B.L., Frigato, T., Helms, V., Grubmuller, H. (2003) The mechanism of proton exclusion in the aquaporin-1 water channel, *J. Mol. Biol.* **333**, 279–293 for more details. (See color plate p. xxxi.)

showed a discontinuous water file through the channel and obvious defects in the structure, particularly at the NPA motifs, because of instability observed through the MD simulations. Further homology modeling between the available structures yielded improved stability in the core of the channel. Simulations of the high-resolution GlpF structure, and the improved homology model of AQP1 both observed continuous water files diffusing through the water channel, illustrated in Fig. 5(b), at rates comparable to those observed experimentally.

In late 2001, a 2.2-Å resolution X-ray crystal structure was obtained of human aquaporin-1. With confidence in the three-dimensional structure, the

simulation studies that followed were able to focus on measuring physical properties of the channel using classical simulation methods, and also tried to pinpoint the origin of aquaporin's ability to transport water at high diffusion rates, while restricting proton transport. The basis of proton transport is a topic better addressed by quantum mechanical simulations, and so combinations of classical dynamics methods with semiempirical methods have been employed by a number of groups to determine the basis for proton exclusion by these channels.

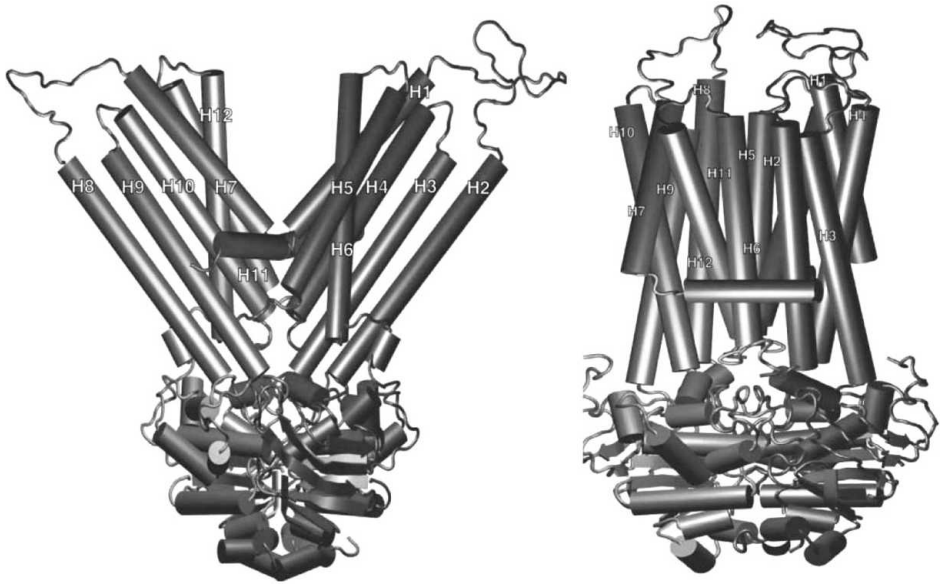
What is particularly exciting about aquaporin as a case study is that the biological function of this protein, to act as a water channel across the cell membrane, occurs at a rate which is accessible to study by the current state of the art in molecular dynamics simulations. Through simulations, researchers were able to point out deficiencies in the low-resolution crystal structures on the basis of structural instability, and because the observed behavior *in silico* did not agree with that measured experimentally. This observation helped to point out the significance of certain structural motifs in the protein (i.e. the reentrant loops with the NPA motif). The evolution of our understanding of the aquaporin structure through experiments, homology modeling, and simulations has lead to similar methods being applied to other aquaporins with yet unsolved structures.

5.3 ABC Transporters and Multidrug Resistance Proteins

Many human proteins of major medical interest are difficult to obtain in large enough quantities for structural studies. The only exceptions have been proteins that occur in large amounts, such as bovine lens protein rhodopsin or Aqp1 from blood (as seen earlier). An emerging theme in membrane protein structural biology over the past years has been the use of bacterial homologs of human proteins, with, as striking examples, several potassium channel structures and several structures of ABC transporters. ATP-binding cassette (ABC) transporters are modular mechanical machines that couple the hydrolysis of ATP with the transport of molecules across membranes. They consist of two nucleotide binding domains (NBDs), two transmembrane domains, and optional additional domains, organized in a varying number of polypeptide chains. Mutations in the genes encoding many of the 48 ABC transporters of human cells are associated with several diseases, including cystic fibrosis. Increased expression of certain ABC transporters is a major cause of resistance to peptide antibiotics, antifungals, herbicides, anticancer drugs, and other cytotoxic agents. Interestingly, ABC transporters probably form the largest group of homologous proteins and exist in all species. In an exciting recent development, three crystal structures of ABC transporters have been determined: MsbA from *Escherichia coli* at 4.5-Å resolution, MsbA from *Vibrio cholera* at 3.8-Å resolution, and BtuCD from *E. coli* at 3.2-Å resolution. In addition, about 10 structures of nucleotide binding domains (NBDs) have been solved as well as ATP binding domains from other proteins. Despite this impressive progress in structural studies, several of the key questions about the basic mechanism of action of ABC transporters are unresolved. Simulations and homology modeling can be used to make some progress toward understanding the dynamics of ABC transporters and to translating the bacterial structures to human homologs like P-glycoprotein.

Molecular dynamics simulation studies have been used to investigate the "real-time" dynamics of the vitamin B_{12} importer BtuCD from *E. coli*, based on the single snapshot captured in the crystal structure. An example of a simulation model that incorporates BtuCD is shown in Fig. 3. In this model, the crystal structure is incorporated in a realistic environment of phospholipids, water, and ions, and simulated for 20 ns, both in the absence and presence of MgATP in the two binding sites. The results demonstrate that the docking of ATP to the catalytic pockets progressively draws the two cytoplasmic nucleotide-binding cassettes toward each other. Movement of the cassettes into closer opposition in turn induces conformational rearrangement of α-helices in the transmembrane domain. The shape of the translocation pathway consequently changes in a manner that could aid the vectorial movement of vitamin B_{12}. These results suggest that ATP binding may indeed represent the power stroke in the catalytic mechanism. Moreover, occlusion of ATP at one catalytic site is mechanically coupled to opening of the nucleotide-binding pocket at the second site. This may indicate that asymmetric behavior at the two catalytic pockets forms the structural basis by which the transporter is able to alternate ATP hydrolysis from one site to the other. While this remains to be tested, this study is an example of the use of dynamics simulations that build on a single crystal structure to obtain more information about the full process the protein is involved in.

The multidrug resistance P-glycoprotein mediates the extrusion of chemotherapeutic drugs from cancer cells. Characterization of the drug binding and ATPase activities of the protein have made it the paradigm ATP binding cassette (ABC) transporter. Although no high-resolution structure is known, P-glycoprotein has been imaged at low resolution by electron cryomicroscopy and extensively analyzed by disulfide cross-linking. Stenham et al. used an interesting combination of approaches to create a molecular model of P-glycoprotein (shown in Fig. 6) that fits with most experimental data from cross-linking and imaging, helps interpret these experiments, and provides insight into possible mechanisms of drug transport. As described earlier, the only ABC transporter structures whose high-resolution structures are known are MsbA and BtuCD. There is no homology between the transmembrane domains of BtuCD and P-glycoprotein, but the homology between MsbA and P-glycoprotein is 23% sequence identity for the transmembrane domains and 51% sequence identity for the nucleotide binding domains. MsbA is the closest known bacterial relative of P-glycoprotein. Unfortunately, the nucleotide binding domains in MsbA are poorly resolved and the structure has a low resolution. In contrast, the nucleotide binding domains in BtuCD are well resolved. The situation is further complicated by the tertiary and quaternary organization of the domains of MsbA, which is not consistent with either the BtuCD crystal or the extensive cross-linking data already published for P-gp. Nevertheless, Stenham et al. have shown that it is possible to generate atomic scale models of P-gp by combining experimental and theoretical methods. Their homology models are based on an MsbA template but with a tertiary organization that reflects the increasingly accepted consensus NBD dimer interface. This model will be useful in designing and interpreting experimental work on P-gp. In turn, results



(a) (b)

Fig. 6 (a) Construction of a molecular model for P-glycoprotein (P-gp). Each half of P-gp was modeled by homology to the crystal structure of MsbA (PDB code 1JSQ), which had been extended to a full atom representation. The two halves of P-gp were assembled such that the NBDs adopt the ATP-dependent orientation observed in MJ0796 (PDB code 1L2T). The constituent domains are individually colored. (b) Reconciliation of cross-linking data with a P-gp model. P-gp-Model-B was generated by rotation of each NBD with respect to its cognate TMD. The final model contains a parallel TMD:TMD interface (blue and gold subunits) and a consensus NBD:NBD interface (green and purple subunits). Adapted from Stenham, D.R., Campbell, J.D., Sansom, M.S.P., Higgins, C.F., Kerr, I.D., Linton, K.J. (2003) An atomic detail model for the human ATP binding cassette transporter P-glycoprotein derived from disulphide cross-linking and homology modeling, *FASEB J.* **17**, 2287–2289. (See color plate p. xxxii.)

from experimental work can be used directly to improve the model, driving an iterative process that may advance our understanding of medically important ABC transporters.

6 Perspectives

Molecular modeling methods have become standard techniques to address biochemical problems at the level of biomolecular structure. A number of factors have contributed to this success. Computers themselves have become vastly more powerful in the past decades. Initially, simulations were restricted to very simple systems on timescales and levels of detail that were typically not adequate to answer specific questions about proteins. With a 10-fold increase in speed every 5 years a wide range of problems is now accessible directly by computer simulation, such as water transport in aquaporins. The fastest folding proteins can now be studied directly

by simulations on the same timescale as the fastest experiments, with unprecedented progress in our understanding of protein folding. Computer graphics hardware has enjoyed a similar increase in speed, enabling complex surface representations of large biomolecular complexes and interactive 3D graphics. A second factor is the improvement in simulation and modeling software, which has led to the development of software that is vastly more user friendly than even a few years ago and runs on commodity hardware instead of exotic (expensive) workstations. A third factor is the improvement in algorithms and parameters that describe interactions between atoms or predict the structure of proteins. With increasing accuracy or more efficient algorithms, molecular modeling is able to answer increasingly more detailed and complicated questions. Finally, the massive advances in experimental studies at the level of biomolecular structure feed back into computer modeling. The expanding database of high-resolution protein structures is a key resource for further development of modeling methods. Advanced single-molecule experiments provide a direct link with simulations that was very rare in the past, and an increasing number of experimental techniques can now be linked to simulation results directly. An example of this is data from nuclear magnetic resonance spectroscopy, which provides both structural and dynamical data on timescales that are comparable to those of simulations.

Because molecular modeling is such a broad area, it is difficult to indicate exactly where most progress can be expected. Technical advances in hardware and software engineering, algorithm and parameter development will continue to increase the number of problems that can be addressed by molecular modeling. These advances will also facilitate incorporation of computationally intense calculations such as QM and QM/MM methods into accessible programs that are user-friendlier to the molecular modeler. The use of Grid technology, distributed computing, and massively parallel commodity-based Beowulf clusters will bring CPU-intensive calculations within reach of an increasing number of researchers, allowing us to study bigger and more complex systems. We expect that important areas of growth will be a stronger link between modeling and experiments, the routine incorporation of modeling and simulation in otherwise mostly experimental studies, and improved methods to study protein–protein interactions and chemical reactions.

Fourier Transformation
Mathematical transformation that provides an analysis of the angular frequencies encoded in a given function.

Nuclear Magnetic Moment
Since atomic nuclei are positively charged, the nuclear spin is proportional to a nuclear magnetic moment.

Nuclear Magnetic Resonance
Owing to their magnetic moment, atomic nuclei interact with external magnetic fields. This enables one to pursue nuclear magnetic resonance (NMR) spectroscopy.

Nuclear Overhauser Enhancement Spectroscopy
''NOESY'': NMR experiment to measure through-space dipolar interactions between the magnetic moments of protons. This allows one to estimate distances between protons in proteins.

Nuclear Spin
The nuclear spin is a nonclassical angular momentum associated with atomic nuclei possessing a spin quantum number larger than zero.

Triple Resonance NMR Experiment
Experiment devised to correlate the chemical shifts of three types of nuclei, that is, ^{1}H, ^{13}C, and ^{15}N.

Nuclear magnetic resonance (NMR) spectroscopy provides unique information about protein structure, dynamics, hydration, and folding in aqueous solution, and has become a pivotal biophysical technique to investigate biological macromolecules. Although the first application of NMR spectroscopy to study proteins date back to the 1960s, its widespread use for proteins was fostered only in the late 1970s and early 1980s by introduction of two-dimensional NMR spectroscopy conducted on spectrometers equipped with superconducting high-field magnets. Advances made in the subsequent 25 years until today have established NMR as an indispensable tool to study even large proteins with molecular masses above 100 kDa. These advances were due to new approaches for efficient production of stable isotope labeled proteins, novel spin relaxation, optimized and rapid sampling of NMR data collection strategies, and the advent of highly sensitive cryogenic probes used for signal detection at field strengths corresponding to 500–900 MHz proton resonance frequency. Recently, the outstanding value of NMR was demonstrated for high-throughput structure determination in the newly emerging field of structural genomics, which makes protein NMR spectroscopy also a key tool for systems biology.

1 Aspects of Multidimensional Protein NMR Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is based on the existence of a nonclassical angular momentum, the *nuclear spin*. All atomic nuclei with a nonzero nuclear spin quantum number possess such a spin. Since nuclei are positively charged, the spin generates a colinearly oriented magnetic moment, which interacts with magnetic fields as compass needles interact with the earth's magnetic field. "Spin-$\frac{1}{2}$ nuclei," with a spin quantum number of $\frac{1}{2}$, exhibit neither electric dipole nor electric quadrupole moments. Hence, spin-$\frac{1}{2}$ nuclei are quite weakly coupled to the environment (often called the *lattice*) via their magnetic dipole moments only: these interact with random fluctuations of magnetic fields that arise from thermal motions. In proteins, the weak coupling enables the observation of coherent spatial reorientations of spins (briefly named *coherences*) about the axis of a strong external magnetic field, B_0, for time periods up to several hundred milliseconds. For a typical study, this allows accurate measurement of hundreds or even thousands of NMR parameters. This wealth of information is unrivaled among solution spectroscopic techniques and is a central reason for the success of modern protein NMR spectroscopy.

Protein NMR relies on the three spin-$\frac{1}{2}$ nuclei ^{1}H, ^{13}C, and ^{15}N. Since these nuclei possess the same spin quantum number of $\frac{1}{2}$, the absolute value of their spin angular momenta is equal. However, owing to varying charges (and charge distributions within the nuclei), the resulting magnetic moments differ greatly. ^{1}H possesses the largest magnetic moment, while the magnetic moments of ^{13}C and ^{15}N are fourfold and tenfold smaller, respectively. Since resonance frequencies scale accordingly, this has far-reaching consequences for the design of protein NMR experiments: highest sensitivity is achieved for experiments starting with proton polarization and ending with proton signal detection. Furthermore, only ^{1}H is 100% abundant in nature, while ^{13}C (natural abundance: ~1%; mainly naturally occurring is ^{12}C, a spin-0 nucleus which is "invisible" in NMR) and ^{15}N (~0.5%; mainly naturally occurring is ^{14}N, a spin-1 nucleus with an electric quadrupole moment that results in broad NMR lines) need to be enriched if a protein has to be studied with more demanding heteronuclear NMR spectroscopy based on ^{13}C and/or ^{15}N.

Radio frequency (rf) pulses created with an rf coil can induce the coherent precession of spin magnetic moments about the axis of an external magnetic field. This precession and its decay can be detected with an rf coil, and the resulting signal ("free induction decay") yields, after Fourier Transformation (FT), a one-dimensional (1D) NMR spectrum. For proteins, the resonance lines provide chemical shifts and, in favorable cases, estimates for scalar spin–spin couplings from resonance fine structures, and nuclear spin relaxation times from line widths. However, owing to the large number of nuclei, 1D NMR spectra of proteins and other biological macromolecules are very crowded. Hence, protein NMR primarily relies on two-, three-, and four-dimensional (2D, 3D, and 4D) spectral information. The high dimensional NMR spectra afford increased spectral resolution and correlate several chemical shifts in a single data set.

A 2D data set is obtained if the signals of a 1D spectrum are modulated by the evolution of an NMR parameter (usually a chemical shift) in an "indirect

dimension'' prior to acquisition (Fig. 1). Fourier transformation along the indirect dimension yields the 2D frequency domain spectrum. In the same fashion, 3D (4D) NMR data sets are obtained by recording many 2D (3D) data sets, which are modulated by an additional NMR parameter. As a result, we have the minimal measurement time, T_m, increasing steeply with dimensionality: acquiring 32 points in each indirect dimension (with one scan per 1D spectrum each second) yields T_m(3D) ~0.5 h, T_m(4D) ~9 h, T_m(5D) ~12 days and T_m(6D) ~1 year. This obstacle for acquiring the highest dimensional NMR spectral information has been named the *NMR sampling problem*.

Figure 2(a) shows a 2D [^{15}N,^{1}H]-correlation spectrum (''COSY''), which was recorded for a ^{15}N-labeled 21-kDa globular protein on a spectrometer operating at 900 MHz ^{1}H resonance

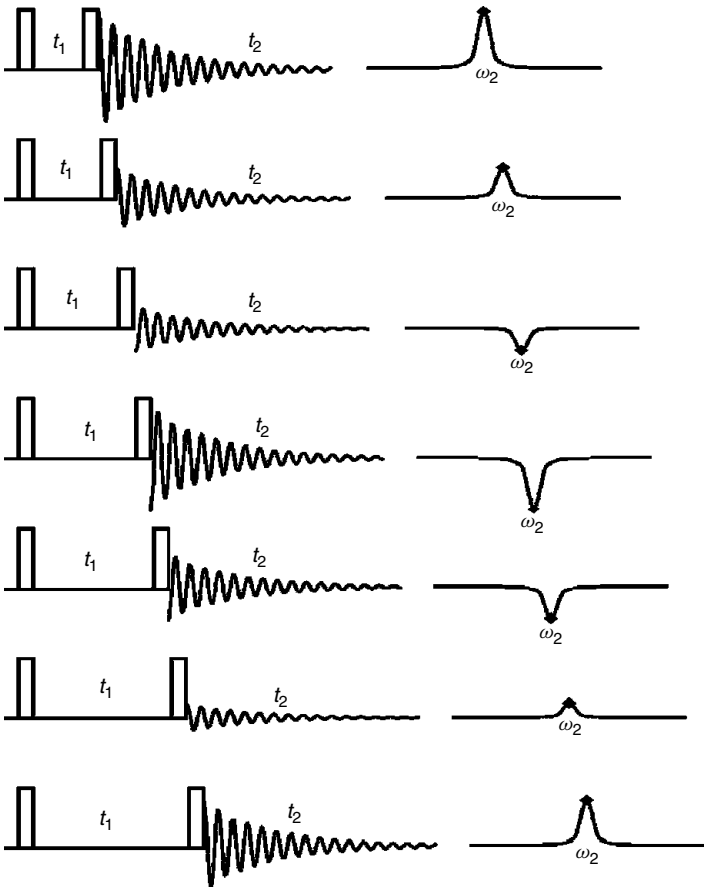

Fig. 1 Principle of 2D NMR. 1D spectra (on the right), obtained after Fourier transformation (FT) of the free induction decays along t_2, are modulated by the evolution of an NMR parameter (e.g. a chemical shift) in an indirect dimension (''t_1''). The frequency domain 2D spectrum is obtained after a second FT along t_1. Courtesy of Jeff Mills.

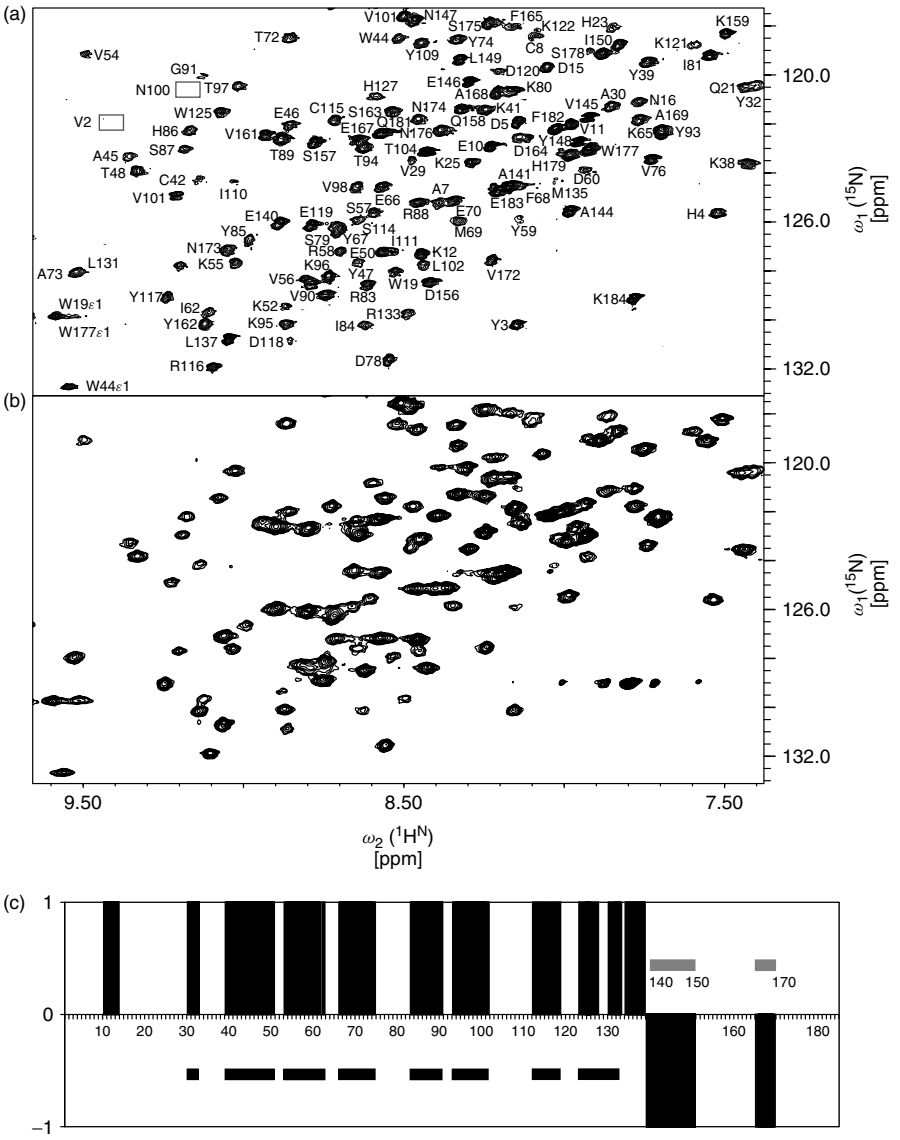

Fig. 2 (a) 2D [^{15}N,^{1}H]-COSY spectrum recorded in the transverse relaxation optimized (''TROSY'') acquisition mode (see Sect. 4) on a 900-MHz Varian INOVA spectrometer (25 °C) for the uniformly ^{15}N-labeled 21-kDa protein FluA(R95K). The peaks are labeled using the one-letter code for amino acids. (b) For comparison, a 2D [^{15}N,^{1}H]-COSY spectrum recorded without ''TROSY'' at 600 MHz is shown. (c) Chemical shift index (CSI) consensus plot for identification of regular secondary structure elements. The eight β-strands forming a β-barrel (black bars) as well as the α-helices (gray bars) are indicated. (a and b are reproduced with permission from Liu, G., Mills, J.L., Hess, T.A., Kim, S., Skalicky, J.J., Sukumaran, D.K., Kupce, E., Skerra, A., Szyperski, T. (2003) Resonance assignments for the 21 kDa engineered fluorescein-binding lipocalin FluA, *J. Biomol. NMR* **27**, 187–188).

frequency. To generate this spectrum, 1D ^{1}H NMR spectra of amide protons are modulated with the chemical shift of the covalently attached ^{15}N nucleus, and one signal is detected for each amino acid residue (except for prolinyl residues and the N-terminal residue). Owing to high intrinsic sensitivity, one can rapidly obtain site-specific information along the entire polypeptide backbone. This feature makes 2D [^{15}N,^{1}H]-COSY (correlation spectroscopy) one of the most important experiments in modern NMR-based structural biology. First, the signal dispersion allows one to assess the degree to which the protein is folded: unfolded polypeptide segments tend to exhibit signals in a comparably narrow range attributed to ''random coils.'' Secondly, the comparison of expected and detected number of signals enables one to investigate if parts of the protein, for example, loops connecting regular secondary structure elements, are affected by slow motional modes in the microsecond to millisecond time range. Such motions quite often lead to broadening of signals beyond detection.

Prior to using NMR spectroscopy for deriving site-specific information on structure or dynamics of proteins, the nuclear magnetic resonances must be ''assigned,'' that is, one has to identify the chemical shifts (see Sect. 3) of spins. Since proteins contain each type of amino acid several times at various positions along the polypeptide chain, it is not sufficient to identify the type of proton (e.g. $^{1}H^{\alpha}$ of glutamate) belonging to a given resonance. Instead, one has to obtain ''sequence-specific'' resonance assignments (e.g. $^{1}H^{\alpha}$ of the glutamate *in position 79*). Obtaining (nearly complete) sequence-specific resonance assignments is generally considered a prerequisite for determining protein structures (see Sect. 5). This so-called ''assignment problem'' is comparable to the crystallographic ''phase problem'' in the sense that a structural interpretation of experimental data depends on solving these problems. Nowadays, sequential resonance assignment of $^{15}N/^{13}C$-labeled proteins relies largely on recording $^{15}N/^{13}C/^{1}H$ triple resonance NMR experiments (Fig. 3). In these experiments, several proton, carbon, and nitrogen chemical shifts are correlated. These originate either from the same, or from two sequentially neighboring residues. Combining the information from the two experiments then allows one to effectively ''walk'' along the polypeptide chain to obtain sequence-specific resonance assignments for backbone (and often $^{13}C^{\beta}$ shifts). Importantly, these chemical shifts can provide the location of regular secondary structure elements (Fig. 2c) without reference to nuclear Overhauser effects (NOEs). The

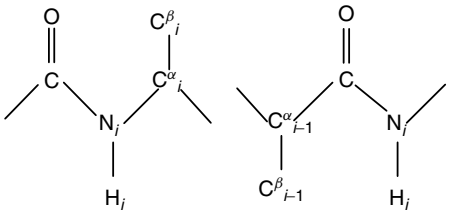

Fig. 3 Example of chemical shifts of nuclei (in color) correlated in triple resonance NMR experiments for obtaining sequence-specific backbone resonance assignments of proteins. A first experiment correlates the shifts of amide proton, nitrogen, α-carbon, and β-carbon within a given residue *i* (on the left). A second experiment correlates the shifts of amide proton and nitrogen of residue *i* with those of the α- and β-carbons of the preceding residue $i-1$. Combining the two experiments allows one to obtain sequence-specific resonance assignments for the backbone (and $^{13}C^{\beta}$ shifts) of the entire polypeptide. (See color plate p. xxix).

backbone NMR experiments are then combined with other experiments to assign resonances of side chains, thus yielding a *complete* protein resonance assignment.

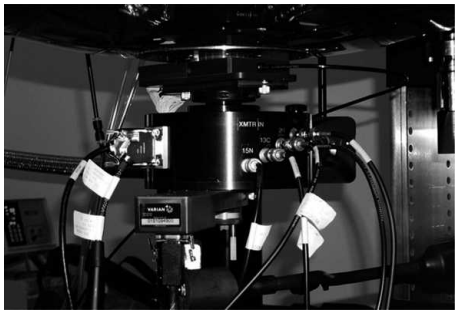
2 NMR Instrumentation

Transitions between nuclear spin states are associated with radio frequency energy quanta that are, at ambient temperature, several orders of magnitude smaller than kT (k and T represent Boltzman constant and temperature). Hence, NMR transitions are *lowest energy* transitions. This results in both, the greatest strength and the greatest weakness of NMR spectroscopy. The strength is due to the fact that the low energy required for observing the system (using the nuclear spins as ''spies'') hardly affects even the subtlest conformational equilibria in their structural and dynamic manifestation. The weakness associated with the low interaction energy is due to the low sensitivity of NMR spectroscopy when compared with, for example, optical spectroscopy. This problem is further aggravated in protein NMR, since slowly tumbling macromolecules exhibit short transverse spin relaxation times and thus exhibit broad resonance lines. Hence, to alleviate this drawback, modern protein NMR depends on using large superconducting magnets (Fig. 4a). In 2005, the largest commercially available magnets have a price tag of about four million US dollars and can induce a ^{1}H resonance frequency of 900 MHz. Apart from increased sensitivity, which scales with ${B_0}^{3/2}$, high magnetic fields yield increased signal dispersion scaling with ${B_0}^N$, where N is the dimensionality of the NMR experiment. A second major breakthrough in hardware development was the construction of cryogenic NMR probes (Fig. 4b). In such probes, the rf coil for signal detection is cooled to about 25 K, which leads to a large reduction in thermal noise in the rf circuitry. In spite of the fact that the insulation between rf coil and NMR sample (which needs to be kept at ambient temperature) reduces the filling factor of the coil, 2 to 3 fold gains in sensitivity can be routinely achieved in protein NMR. This corresponds to about 5 to 10 fold reduced NMR data collection times, so that rapid NMR data collection techniques (see Sect. 4) are best suited to take advantage of the high sensitivity of such probes.

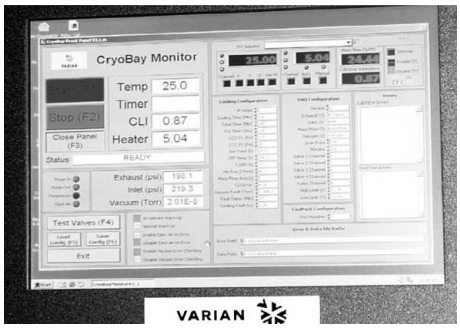
3 Experimental Protein NMR Parameters

Protein NMR spectroscopy aims at measurement of parameters, which provide the desired structural and/or dynamic information of a system under consideration. *Chemical shifts* are due to the site-specific shielding of the external magnetic field at the location of the nucleus. Hence, chemical shifts depend on the covalent and conformational environment in which a spin is embedded and are affected by long-range electrostatic and ring current effects. The dispersion of chemical shifts arising from the folding of a polypeptide into a tertiary structure is pivotal for using NMR: without such conformation-dependent dispersion, one could not resolve the site-specific information. Chemical shifts are routinely measured in multidimensional NMR spectra (see Sect. 1), and the resonance assignment is quite generally considered a prerequisite for the site-specific interpretation of other NMR parameters described below. Importantly, backbone and $^{13}C^{\beta}$ chemical shifts provide the location of the regular secondary structure elements

(a)



(b)



(c)

Fig. 4 Modern high-field NMR equipment used for protein NMR spectroscopy. (a) Spectrometer at the New York Structural Biology Center operating at 900 MHz ^{1}H resonance frequency (Courtesy of David Cowburn). (b) Cryogenic probe installed at the University at Buffalo high-field NMR facility (Courtesy of Dinesh Sukumaran). The probe is inserted from below in the magnet, and its rf coil is cooled to 25 K, as can be read off the monitor shown in (c).

(Fig. 2c). Moreover, chemical shifts are not isotropic, that is, the shielding of the external magnetic field depends on the orientation of the molecule relative to the field. Chemical shifts are thus accurately described by using a ''chemical shift tensor.''

Scalar nuclear spin–spin couplings, J, arise from the through-bond coupling of the nuclear magnetic moments. The *J*-coupling is the most important interaction used to devise multidimensional experiments for measurement and correlation of chemical shifts (Fig. 2a). Moreover, three-bond *J*-couplings are related through the ''Karplus-relations'' to dihedral angles and thus encode valuable structural information.

^{1}H$-^1$H NOEs arise from through-space coupling of the magnetic dipole moments of protons. Owing to the r^{-6} dependence of the dipolar coupling (with r being the distance between two protons), the measurement of NOEs in [^{1}H,^{1}H]-NOESY (nuclear Overhauser enhancement spectroscopy) allows one to estimate distances between protons: NOEs effectively constitute a ''molecular ruler.'' Thus, having a large number of such ^{1}H$-^1$H distance constraints, one can calculate

three-dimensional molecular structures (see Sect. 5).

Residual dipolar couplings (RDCs) arise if a protein is partially aligned in a dilute liquid crystalline medium. Notably, for paramagnetic metalloproteins, such alignment takes place at high magnetic fields without the presence of a liquid crystalline medium. Owing to the partial alignment, the dipolar through-space coupling between dipole moments is not completely averaged out, as in the case of molecules tumbling in an isotropic medium. RDCs encode orientational constraints, that is, they provide information regarding the orientation of the internuclear axis of the dipolarly coupled nuclei relative to the principle axes of the alignment tensor. RDC-derived orientational constraints are thus quite distinct from – and complementary to – NOE-derived distance constraints for NMR structure calculation and validation. Since RDCs depend on motional averaging, they also provide valuable information about internal motional modes.

Nuclear spin relaxation parameters, such as longitudinal/transverse spin relaxation times and heteronuclear Overhauser effects reflect dynamic features of the protein under investigation. Hence, the majority of our insights into protein dynamics, be it overall rotational reorientation or internal motions, have thus far been obtained from measurement of these parameters.

4 Recently Developed Techniques

The introduction of (1) multidimensional triple resonance NMR and heteronuclear resolved [^{1}H,^{1}H]-NOESY, and (2) efficient ^{13}C/^{15}N labeling and protein deuteration protocols until the mid 1990s, made NMR a key tool to study structure and dynamics of proteins up to about 15 to 20 kDa. During the last decade, new NMR techniques were introduced to study much larger systems and to dramatically increase NMR data collection speed.

Transverse relaxation optimized NMR spectroscopy (TROSY) takes advantage of the mutual cancellation of nuclear spin relaxation pathways in slowly tumbling macromolecules studied at high magnetic fields (Fig. 5). 2D [^{15}N,^{1}H]-TROSY (Fig. 2a), and triple resonance NMR variants thereof, are most prominent and shall be discussed. Both, the ^{15}N and the ^{1}H nucleus of a polypeptide backbone H−N moiety exhibit substantial chemical shift anisotropy (CSA). As a result, two major pathways for transverse ^{15}N and ^{1}H spin relaxation are encountered: one owing to the dipolar ^{1}H−^{15}N interaction and the other owing to the CSA. While spin relaxation due to random fluctuation of the shielding is independent of spin states, the sign of the fluctuating local B-field arising from the spatial modulation of the dipolar interaction does depend on spin states. Hence, the transverse relaxation rate of a given ^{15}N or ^{1}H spin is accelerated when both the CSA and dipolar interaction random B-field fluctuations add up, whereas the transverse rate is reduced in cases where the two random fluctuations (partially) cancel. Since short transverse relaxation times lead to broad NMR lines, this phenomenon can be directly monitored in a 2D [^{15}N,^{1}H]-COSY experiment in which the one-bond ^{1}H−^{15}N J-coupling (∼95 Hz) places the various transitions into separate spectral regions (no "^{15}N−^{1}H" decoupling; Fig. 5). Out of the four transitions registered for a given ^{15}N−^{1}H moiety, one is broadened in both dimensions, two are broadened in one dimension but narrow in the other,

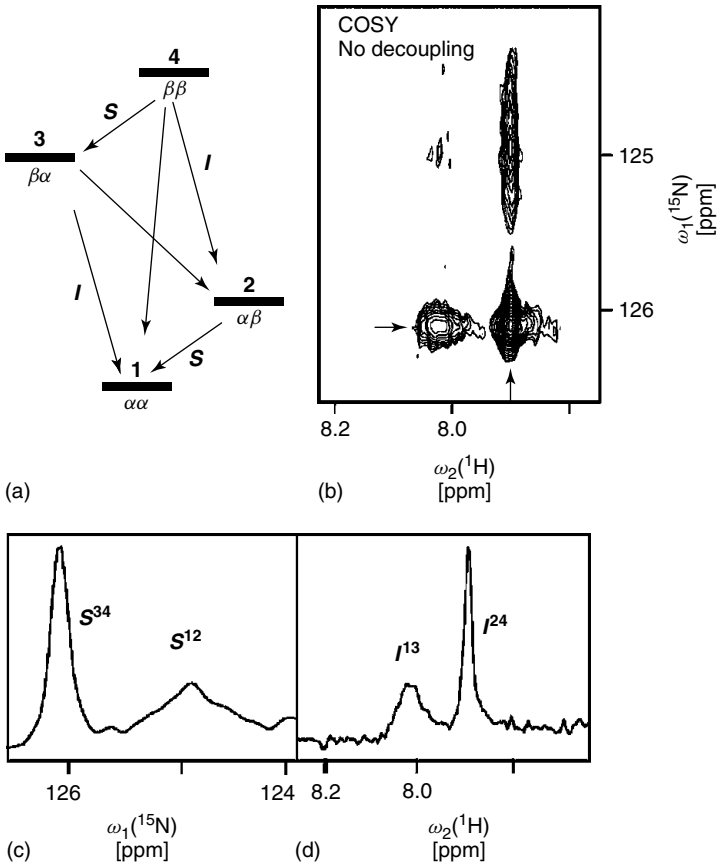


Fig. 5 (a) Energy levels of a scalarly coupled two spin-$\frac{1}{2}$ system IS (for example, $I = {}^{1}H$, $S = {}^{15}N$). The nuclear spin states are indicated as "α" and "β" depending on the orientation of the magnetic moments relative to the external magnetic field. (b) Cross-peak registered for a backbone N−H group in a [^{15}N,^{1}H]-COSY spectrum recorded (without decoupling of the $^{15}N-^{1}H$ scalar coupling interaction) for the 110-kDa protein aldolase at 20 °C. In this protein preparation, aliphatic and aromatic ^{1}H were replaced by ^{2}H ("deuterated") in order to eliminate dipolar interactions between backbone amide and carbon-bound protons. (c) and (d) 1D cross sections taken along ω_1 and ω_2 at the positions indicated in (b) by arrows. Comparison of line widths of the four components reflects the different transverse relaxation rates between the transitions shown in (a). A [^{15}N,^{1}H]-TROSY experiment relies on selecting the two transitions S^{34} and I^{24}. Reproduced with permission from Pervushin, K. (2000) Impact of transverse relaxation optimized spectroscopy (TROSY) on NMR as a technique in structural biology, *Q. Rev. Biophys.* **33**, 161–197.

and one is narrow in both dimensions. TROSY relies on selecting the latter narrow component, while discarding the others.

Since CSA-based transverse relaxation scales with $B_0{}^2$, TROSY is best performed at a magnetic field strength where the two relaxation pathways cancel (nearly) entirely. Fortunately, ^{1}H and ^{15}N CSA are of comparable magnitude (in Hz), so that about the same optimal TROSY field strength is predicted for both ^{1}H and ^{15}N transitions (corresponding to 900–1100 MHz ^{1}H resonance frequency). This makes triple resonance [^{15}N,^{1}H]-TROSY feasible. In conjunction with protein deuteration, this allows one to study systems with molecular masses well above 100 kDa, that is, up to about an order of magnitude larger than what could be approached without TROSY.

Methodology for rapid acquisition of NMR data focuses on resolving the ''NMR sampling problem'' (see Sect. 1), that is, on making high dimensional spectral information available at short measurement times. Currently, two broader classes of rapid data sampling approaches can be distinguished.

First, *G-matrix Fourier Transform* (GFT) NMR is a projection technique, which can also serve to reconstruct the higher-dimensionality parent NMR spectra one would obtain if no projection is applied. GFT NMR is based on the joint sampling of indirect chemical shift evolution periods that leads to signals with a multiplet fine structure, encoding several chemical shifts. A ''G-matrix transformation'' is applied in order to sort the components of the shift multiplets into subspectra, so that the peaks in each subspectrum encode a distinct linear combination of the jointly measured chemical shifts (Fig. 6). Hence, monitoring of chemical shifts in FT NMR

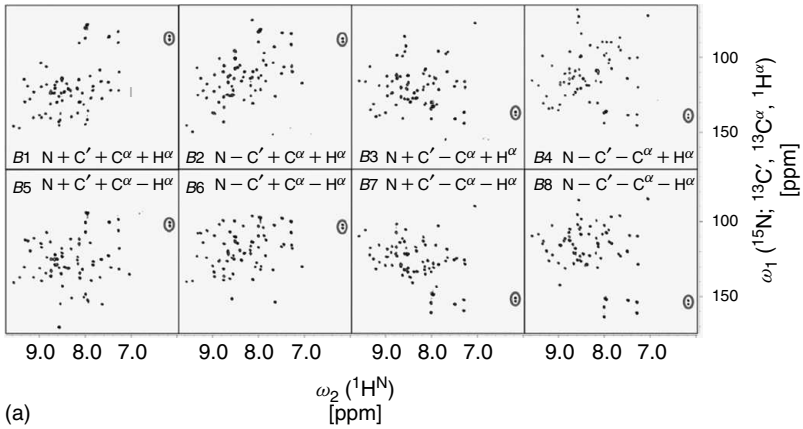

Fig. 6 15 2D planes constituting a (5,2)D HACACONHN GFT NMR experiment, which can provide the information of a 5D FT NMR experiment within less than an hour of measurement time. The type of linear combination of chemical shifts detected in a given plane is indicated. (a) The basic spectra. (b), (c) and (d) First, second, and third order central peak spectra in which linear combinations with fewer shifts are monitored to resolve assignment ambiguities. (e) Cross sections showing that signals do not broaden with an increasing number of shifts being jointly sampled. Reproduced with permission from Kim, S., Szyperski, T. (2003) GFT NMR, a new approach to rapidly obtain precise high dimensional NMR spectral information, *J. Am. Chem. Soc.* **125**, 1385–1393.

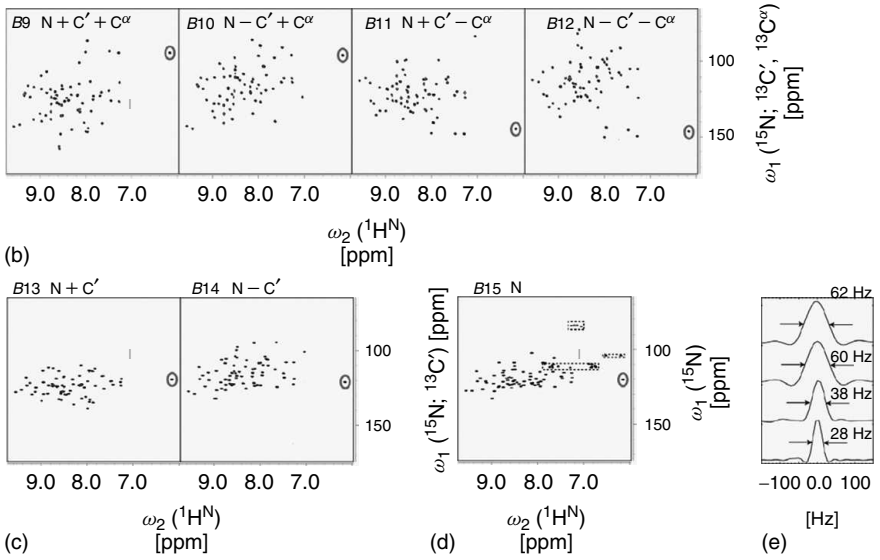

Fig. 6 (*Continued*)

spectroscopy is replaced in GFT NMR spectroscopy by measuring permutations of linear combinations of chemical shifts. This leads to approximately an order of magnitude reduction of measurement times *per* indirect dimension that is included in the joint sampling scheme.

Second, *single-scan acquisition* of 2D NMR spectra, named *ultrafast NMR*, was introduced. This approach constitutes an interface between high-resolution NMR and magnetic resonance imaging. The indirect chemical shift evolution is spatially encoded by use of pulse-field gradients applied along the axis of the external magnetic field B_0, and then "read out" together with the chemical shift evolution in the direct dimension in a single scan. In principle, this single-scan acquisition scheme can be extended to an arbitrary number of dimensions, that is, to the implementation of 3D and 4D single-scan acquisition. For proteins, however, reduced sensitivity currently limits this concept to the use of 2D single-scan acquisition. Importantly, ultrafast NMR is the only technique providing multidimensional NMR spectral information without sampling of indirect chemical shift evolution periods (Fig. 7). This allows one to acquire a multidimensional spectrum within the fraction of a second, and enables high-throughput acquisition of such spectra at unprecedented speed.

5 Structure Determination

NMR solution structures are usually solved in several major steps as outlined in the following. At the outset, a suitable sample (usually about 500 µL of a 1-mM protein solution) is prepared. Nowadays, both prokaryotic and eukaryotic high-yield overexpression systems serve for that purpose. If the molecular weight of a protein exceeds about 10 kDa, labeling with the NMR active spin-$\frac{1}{2}$ nuclei ^{13}C and ^{15}N is required to resolve spectral

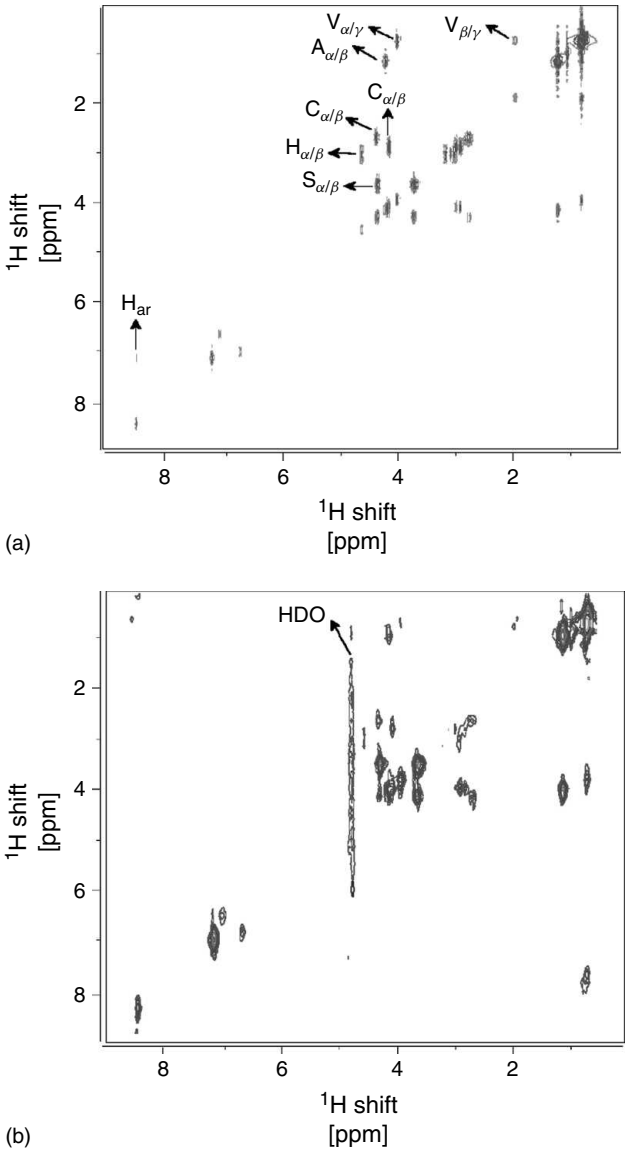

Fig. 7 Comparison of a conventionally acquired 2D [^{1}H,^{1}H] total correlation spectrum (a) acquired in 90 min for the hexapeptide CSHAVC (in the one-letter amino acid code) with the corresponding ultrafast congener recorded in 150 ms (b). In the upper panel, resonance assignments are indicated. Courtesy of Lucio Frydman.

overlap and to measure heteronuclear chemical shift correlations. For systems above about 25 kDa, one would usually consider deuterating the protein.

The sample thus obtained is used to record a set of multidimensional NMR experiments at temperatures around 30 °C. These allow (nearly) complete sequential NMR assignments to be obtained, and the conformation-dependent dispersion of the shifts enables one to derive experimental constraints for the NMR structure calculation. In most cases, structures are calculated on the basis of $^1H-^1H$ upper distance limit constraints derived from [^{1}H,^{1}H]-NOESY (Fig. 8).

The assignment of NOESY cross peaks and the calculation of the NMR structure is quite generally pursued in an iterative fashion. An initial set of distance constraints, which can be unambiguously obtained from the chemical shift data alone, is used to determine a low-resolution description of the protein. In turn, this initial structural model allows one to resolve the remaining NOE assignment ambiguities. This improves the precision of the structural model and allows the identification of yet additional constraints in the next round. Iterations involving structure calculations and identification of new constraints are usually pursued until (nearly) all experimentally derived constraints are in agreement with a bundle of protein conformations representing the NMR solution structure, in which conformational

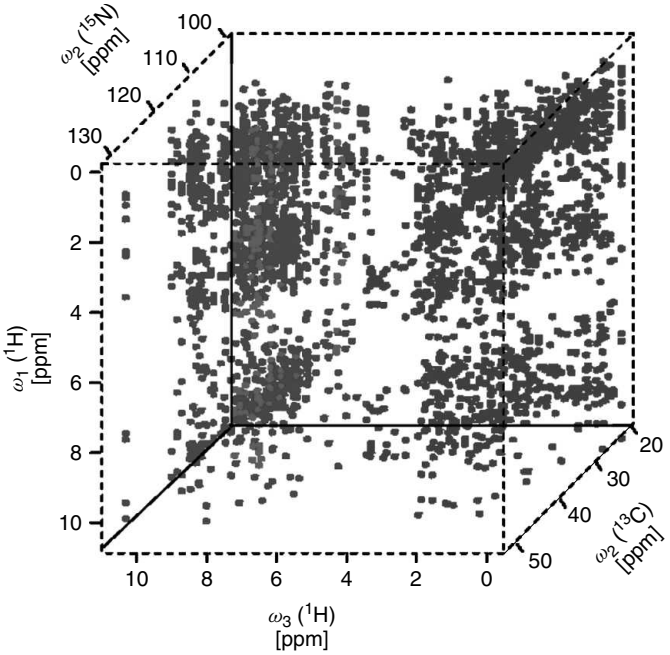

Fig. 8 Cube with dots representing NOEs detected in 3D heteronuclear resolved [^{1}H,^{1}H]-NOESY, which were used for calculating the NMR solution structure of YqfB shown in Fig. 9. variations reflect the precision of the NMR structure determination. Finally, the NMR structure can be refined using molecular force fields, which in essence reflect our knowledge about conformational preferences in proteins.

In order to sample the ''conformational space'' allowed by experimental constraints, NMR structures are usually represented by an ensemble of conformers (typically ~10–30). Various representations (Fig. 9) are used to (1) display the structural information and (2) indicate the local and global precision of the structure determination, which is reflected by rmsd values calculated for sets of atom

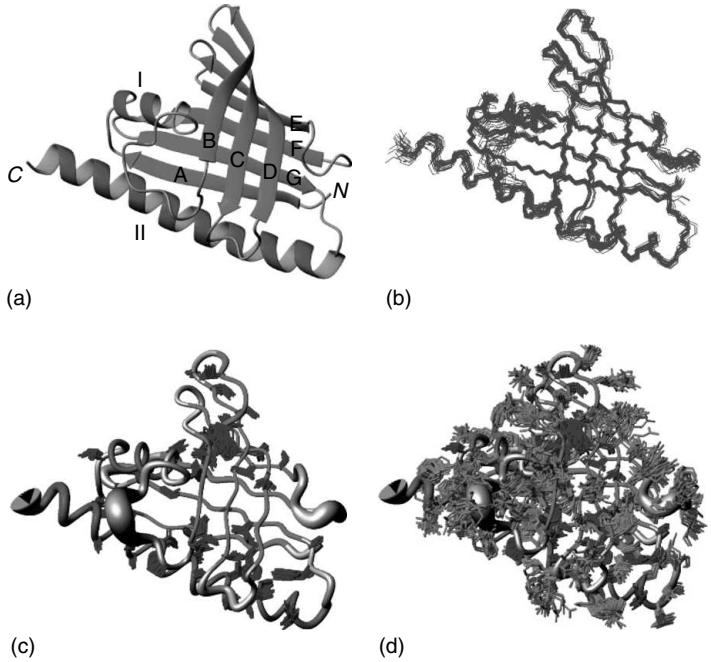

Fig. 9 Commonly used representations of NMR solution structures, exemplified for the 18-kDa Northeast Structural Genomics consortium target protein CC1736. (a) Ribbon drawing of the conformer exhibiting the smallest residual constraints violations. α-Helices and β-strands are depicted, respectively, in red/yellow, and cyan. (b) Superposition of the polypeptide backbone of the 20 conformers chosen to represent the NMR solution structure. The higher precision of the atomic coordinates of the regular secondary structure elements is apparent when compared with the loops. (c) The polypeptide backbone is represented by a spline function through the mean C^{α} coordinates, where the thickness represents the rmsd values for the C^{α}-coordinates after superposition of the regular secondary structure elements for minimal rmsd. The superpositions of the best defined side chains of the molecular core are shown in green to indicate the precision of their structural description. (d) Same as in (c), also showing the superposition of the more flexibly disordered side chains on the protein surface. The protein sample was provided by Drs. Acton and Montelione, Rutgers University. Courtesy of Yang Shen. (See color plate p. xlv).

positions for the ensemble of conformers. Additional criteria, such as the number and size of residual constraint violations or the completeness of stereo-specific resonance assignments, can be used to assess the quality of an NMR structure.

6 Dynamics

Proteins are not rigid but quite dynamic biological macromolecules. In fact, the internal mobility of proteins is of key importance for their function. Nuclear spin relaxation experiments provide unique insights into protein dynamics on the subnanosecond to millisecond timescale. This is because the KHz to MHz random magnetic field fluctuations associated with the motions can be monitored by measuring relaxation parameters. In particular, for ^{15}N, ^{13}C, and ^{2}H-labeled proteins, the measurement of corresponding nonproton relaxation parameters can afford a rather complete coverage of the entire protein.

In a typical protein dynamics study, longitudinal (T_1) and transverse relaxation times (T_2) and heteronuclear Overhauser effects are measured. These measurements can be complemented by use of multidimensional exchange spectroscopy, which provides information regarding very slow motional modes on the $\sim$100 ms timescale. The first key challenge that is encountered for proper interpretation of relaxation parameters is the dissection of the impact arising from the overall rotational reorientation and the internal motional modes.

While the overall tumbling of the protein is important for ''finding'' an interaction partner, the internal motional modes are likely the key to linking function with dynamics. Proteins are usually not of spherical shape, so that their overall tumbling can be highly anisotropic. Any failure to accurately consider this anisotropy leads to a biased picture of the internal motions. Once the overall tumbling properties of a protein are known, the proper selection of an internal motional model remains as the second key challenge. In the so-called ''model-free'' approach, the internal motional mode is described by a minimal set of two parameters: an order parameter reflecting spatial motional restriction and a correlation time. Importantly, the model-free approach is limited to situations in which the internal motions occur on a faster timescale than the overall tumbling. In contrast, detailed assumptions on the nature of the internal motions are made within the framework of analytical models. These are inferred from either intuition or molecular dynamics simulations.

Comparable to reaction mechanisms in chemical kinetics, motional models can never be truly ''proven'' by measurement of spin relaxation parameters. Instead, one can only attest consistency between model and experimental parameters. This is because the complexity of possible spatial motional modes far exceeds the complexity that can be encoded in a rather small number of scalar relaxation parameters. In the same spirit, a more extensive body of data, for example, relaxation parameters measured for various types of nuclei at different magnetic field strengths, allows one to develop more refined multiparameter motional models. Very recently, the measurement of RDCs (see Sect. 3) has been established as a valuable complement to characterize protein dynamics.

Among the currently better characterized motional modes are low-amplitude

segmental motions of loops, large-amplitude flipping of aromatic rings and disulfide bonds, as well as the relative motion of entire domains in multidomain proteins. Moreover, important progress has been made in recent years to link the investigation of protein motion with functional aspects.

7 Hydration

Proteins have evolved in aqueous solution, and their surface interacts with water molecules. Hence, protein hydration plays a key role for understanding structure, dynamics, and function of proteins. In particular, macromolecular recognition involves protein surfaces: the hydration water molecules need to be ''stripped off'' prior to the formation of direct contacts between biological molecules. Hence, thermodynamics and kinetics of protein hydration deserve proper consideration in structural biology. Two NMR techniques provide complementary insights into protein hydration: measurement of $^{1}H-^{1}H$ NOEs between water molecules and protein, and measurement of ^{17}O and ^{2}H nuclear spin relaxation times at different magnetic field strengths.

For a few selected systems, such studies have shown that more than 95% of the water molecules being in contact with the protein surface are *less than* twofold motionally retarded compared to bulk water molecules. Hence, it appears that stripping off the hydration layer can hardly constitute a rate-limiting step for biomolecular interactions. This finding has evidently far-reaching consequences for understanding the kinetic properties of biological systems. In contrast to the very mobile hydration water molecules with ''lifetimes'' on the picosecond timescale, water molecules with longer lifetimes on the millisecond timescale have been identified and characterized. These may well play an integral structural role for proteins.

8 Folding

The rules governing the folding of a protein from an ensemble of ''random coil'' state into its native, functional conformation remain a major enigma of structural biology. NMR spectroscopy has been extensively employed to investigate thermodynamics and kinetics of protein folding. Measurement of chemical shifts (see Sect. 3), spin relaxation parameters (see Sect. 7), exchange spectroscopy (see Sect. 6), as well as determination of backbone amide proton–deuteron exchange rates can provide valuable insights. The majority of NMR studies focused on a few small model systems. These studies fostered the development of intriguing theoretical concepts shaping our view of how protein folding may take place, but have as yet not lead to algorithms enabling one to predict protein structure from sequence. In fact, even the existence of a concise algorithm to predict protein structure, for example, from first physical principles, could be called in question. John von Neumann noted in the framework of his automata theory, that systems may exhibit a degree of complexity, which is so high that their (empiric) description represents the easiest approach to assess them. Such complex systems have subsequently been named *von Neumann systems*, and one may ask the question whether proteins are possibly such systems. If so, it appears that the solution of the protein folding problem through structural

genomics (see Sect. 9) might be the most viable way to proceed. Notably, all methods currently available for ''*ab initio*'' prediction of protein structures, that is, without direct reference to an experimental template, rely on our empiric knowledge of protein structures. Recently, NMR studies have also proven the common existence of intrinsically unstructured but functional proteins, and showed that folding of proteins may take place upon binding to their physiological target molecules.

9 Structural Genomics

Since the genetic code is known, genomic DNA sequences can provide the amino acid sequence of all proteins encoded in a genome. However, since the protein folding problem (see Sect. 8) is not solved, the three-dimensional structure of the proteins cannot be inferred from sequence alone. One central aim of the new discipline of ''structural genomics'' is to make available at least one experimentally determined protein structure for each naturally occurring family of sequence homologs. This shall allow one to (1) homologically model the remaining members of the family using an experimental X-ray or NMR structure as a template, and (2) support the functional annotation of the gene encoding the protein. One may thus argue that structural genomics corresponds to seeking a ''semi-empirical'' solution of the protein folding problem.

Structural genomics relies on high-throughput structure determination

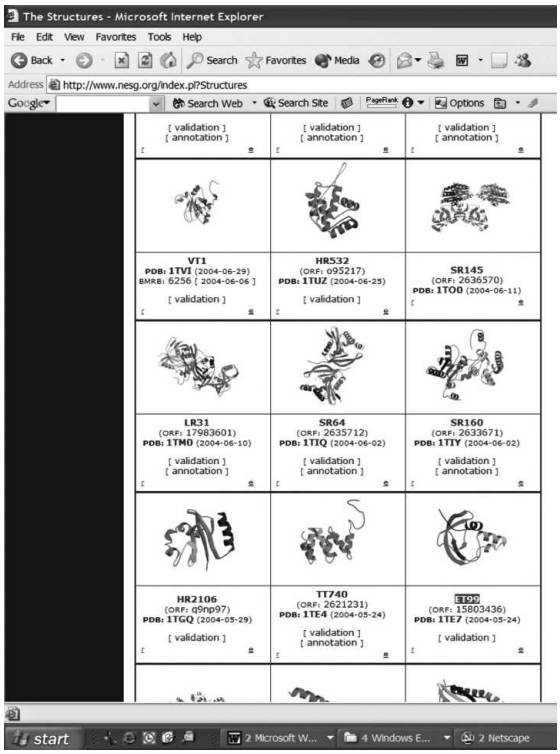

Fig. 10 ''Structure gallery'' accessible at the Web site of the Northeast Structural Genomics consortium in the United State (http://www.nesg.org), documenting successful implementation of a high-throughput NMR structure production pipeline.

(Fig. 10). Protein NMR spectroscopy has only very recently been shown to be a valuable technique for structural genomics (and thus also for systems biology). The ability to achieve protein structure determination (see Sect. 5) in high throughput depends primarily on: (1) sensitive high-field NMR spectrometers equipped with cryogenic probes (see Sect. 2); (2) methodology for rapid NMR data acquisition (see Sect. 4); (3) software for efficient analysis of NMR spectra and fast structure calculation; and (4) methods for automated structure quality assessment, validation, and data bank deposition. The setup of an efficient NMR-based structural genomics pipeline thus requires development of methodology, which strengthens the scientific infrastructure available for NMR-based structural biology in general.

Keywords

Fractionation
The process of separating different proteins based on differences in their properties, such as size, charge, shape, solubility, and binding properties.

Inclusion Body
An insoluble form of a recombinant protein often observed when the protein is overproduced in a bacterial expression host.

Protein
A macromolecule formed by the covalent joining of amino acids to make a polypeptide. The properties of a protein are determined by the number and sequence of its amino acids, and how the polypeptide chain folds into a native structure. Proteins can function as enzymes, as structural components, or as regulators.

Protein Refolding
Protein in an inclusion body is solubilized with a denaturant and then the denaturant is removed to allow the protein to reform its native structure, determined by its primary sequence, and its biological activity.

Protein purification is the process of separating a given protein from all the other proteins, nucleic acids, polysaccharides, lipids, metabolites, and other small molecules in a cell extract. This purification is done ideally with reasonable speed, yield, final purity, and economy, while retaining the biological activity and chemical

and structural integrity. A purification scheme involves a series of fractionation steps that exploit the many differences in the properties of the protein of interest and the other components in the mixture. Design of such fractionation steps must take into account the molecular forces that determine molecular interactions between proteins and various materials used in purification. Care must be taken to prevent inactivation, degradation or absorptive losses during the purification. In recent years, most researchers purify recombinant proteins whose genes have been cloned into an expression vector and expressed in a suitable expression host organism, often the bacterium *Escherichia coli*. The use of purification tags to aid in affinity purification is common. Sometimes, the overproduced protein is found as an insoluble inclusion body that must be isolated, solubilized by denaturants, and then refolded.

1 Introduction

The magnitude of the challenge of protein purification becomes clearer when one considers the mixture of macromolecules present in a cell extract. In addition to the protein of interest, several thousand other proteins with different properties are present in the extract, along with nucleic acids (DNA and RNA), polysaccharides, lipids, and small molecules. The proteins present in the bacterium *Escherichia coli* may be dramatically visualized after resolution by two-dimensional gel electrophoresis as shown in Fig. 1. A given protein may be present at more than 10% or at less than 0.001% of the total protein in the cell. Enzymes are found in different states and locations: soluble, insoluble, membrane bound, DNA bound, in organelles, cytoplasmic, periplasmic, and nuclear. The challenge, therefore, is to separate the protein of interest from all of the other components in the cell, especially the unwanted contaminating proteins, with reasonable efficiency, speed, yield, and purity, while retaining the biological activity and chemical integrity of the polypeptide.

Sections 1 to 6 provide background on classical protein fractionation and purification; that is, the isolation of a protein from its natural source. Sections 7 and 8 give a brief introduction to overproduction and purification of recombinant proteins cloned and overexpressed in a bacterial host expression system.

2 Types of Molecular Interactions and Variables that Affect Them

With regard to protein structure and stability and the interaction between an individual protein and other proteins, DNA, or materials used in protein purification, one must understand the molecular forces involved and how the strength of these forces varies as one varies conditions such as temperature, pH, and ionic strength of a solution. The atomic interactions that seem to be the most important with regard to protein interactions are hydrogen bonds, hydrophobic interactions, and ionic interactions. These are described briefly below.

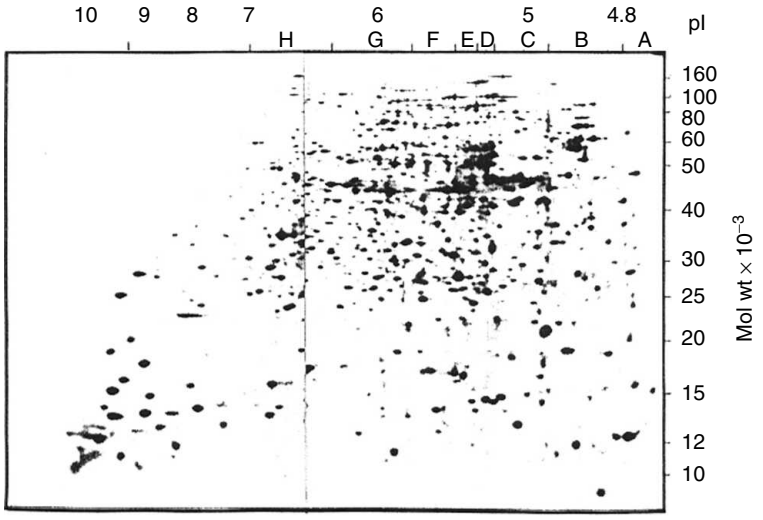

Fig. 1 *E. coli* proteins resolved on a two-dimensional gel. The approximate isoelectric point and molecular weight scales are indicated. *E. coli* K12 strain W3110 was labeled with $^{35}SO_4$ during growth in glucose minimal medium at 37 °C. A composite autoradiogram was made from nonequilibrium (*left side*) and pH 5–7 (*right side*) isoelectric focusing gels. (Adapted, with permission, from Neidhardt, F.C., Phillips, T.A. (1985) The Protein Catalog of *E. coli*, in: Celis, J.E., Bravo, R. (Eds.) *Two-Dimensional Gel Electrophoresis of Proteins*, Academic Press, New York, pp. 417–444.)

2.1 Hydrogen Bonds

Hydrogen bonds (Fig. 2) occur when a proton is shared between a proton donor (−NH and −OH) and a proton acceptor (O=C− and :N−). Optimal hydrogen bonds have a linear geometry and a distance between the donor and acceptor atoms between 2.6 and 3.1 Å. Hydrogen bonds are stronger at low temperature and are weakened as the temperature is raised.

2.2 Hydrophobic Interactions

Nonpolar residues (isoleucine, leucine, valine, phenylalanine, and tryptophan) cannot make favorable hydrogen bonds with water. In order to avoid water, they tend to come together in a so-called hydrophobic interaction (see Fig. 2) usually resulting in their being buried in the interior of a protein. Hydrophobic interactions are strengthened at high salt and high temperature.

2.3 Ionic Interactions

Ionic interactions (see Fig. 2) occur between charged molecules, with like charges repelling and opposite charges attracting. The force of the electrostatic interaction is given by an approximation of Coulomb's law, $E = Z_A Z_B e^2 / D r_{AB}$, where r_{AB} is the distance between two charges, A and B, Z_A, and Z_B are their respective number of unit charges, e is one

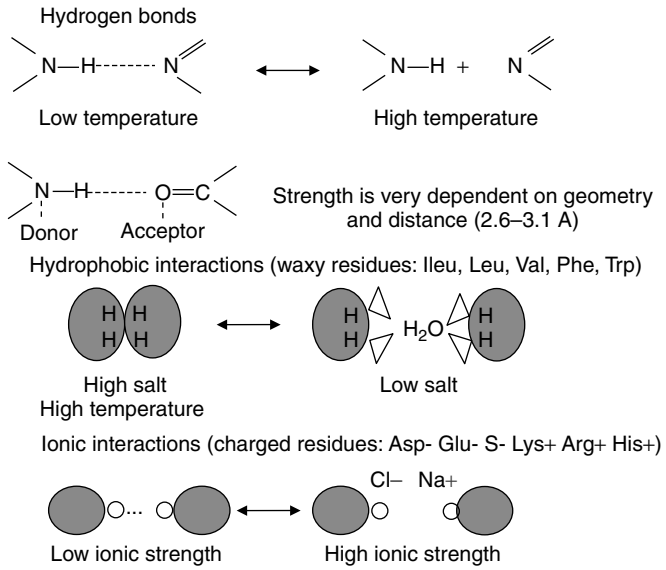

Fig. 2 Hydrogen bonds, hydrophobic interactions, ionic interactions.

unit of electronic charge, and D is the dielectric constant of the solvent. The strength of ionic interactions is therefore inversely proportional to the distance between the charges and the dielectric constant of the solvent, which varies from 2 in nonpolar solvents like hexane to 80 in highly polar solvents such as water. Ionic interactions are weakened as the ionic strength of the solvent increases and the charge is shielded by counterions. Ionic interactions are affected by the pH of the solution, since pH determines the number of charged residues.

2.4 Variables that Affect Molecular Forces

One can vary conditions to affect the relative strength of the above molecular forces. One can easily vary temperature, ionic strength, ion type, dielectric constant, and pH. In a few cases, researchers have also varied pressure.

3 Protein Properties that Can Be Used as Handles for Purification

The reason one is able to purify one protein from a mixture of thousands of proteins is that proteins vary tremendously in a number of their physical and chemical properties. These properties are the result of proteins having different numbers and sequences of amino acids. The amino acid residues attached to the polypeptide backbone may be positively or negatively charged, neutral and polar, or neutral and hydrophobic. In addition, the polypeptide is folded in a very definite secondary structure (α-helices, β-sheets, and various turns) and tertiary structure to create a unique size, shape, and distribution of residues on the surface of the protein. By exploiting the differences in properties between the protein of interest and other proteins in the mixture, one can design a rational series of fractionation steps. These properties include the following.

3.1 Size

Proteins may vary in size from peptides of a few amino acids (with molecular weights of a few hundred) to very large proteins containing over 10 000 amino acids (with molecular weights of over 1 000 000). Most proteins have molecular weights in the range 10 000 to 150 000 (see Fig. 1). Proteins that are part of multisubunit complexes may reach much larger sizes. Proteins are often fractionated on the basis of size (really on the basis of effective radius or Stokes' radius) by passing down a gel-filtration column (or size-exclusion column (SEC). The column is filled with porous beads with characteristic pore sizes. The largest proteins cannot penetrate into the bead and are excluded and elute first in what is called the void or excluded volume. Very small proteins and salts easily pass in and out of the beads and see the entire volume of the column (the column volume). Other intermediate-sized proteins elute between the void and the column volume based on how much time they spend outside and inside the beads.

3.2 Shape

Protein shapes range from approximately spherical (globular) to quite asymmetric. The shape of a protein influences its movement through a solution during centrifugation, through small pores in membranes, into beads during gel filtration, or through gels during electrophoresis. For example, consider two monomeric proteins of the same mass where one is spherical and the other is cigar shaped. During centrifugation through a glycerol gradient, the spherical protein will have a smaller Stokes' radius and, thus, will encounter less friction as it sediments through the solution. It will sediment faster, and thus, appear to be larger than the cigar-shaped protein. On the other hand, during size-exclusion chromatography, the same spherical protein with its smaller Stokes' radius will more readily diffuse into the pores of a gel-filtration bead and will elute later, thus appearing smaller than the cigar-shaped protein.

3.3 Charge

The net charge of a protein is determined by the sum of the positively and negatively charged amino acid residues. If a protein has a preponderance of aspartic and glutamic acid residues, it has a net negative charge at pH 7 and is termed an acidic protein. If it has a preponderance of lysine and arginine residues, it is considered to be a basic protein. The equilibrium between charged and uncharged groups and hence the charge of a protein is determined by the pH of the solution. The charge of the ionizable groups found on unmodified proteins as a function of pH is shown in Table 1. Generally, one used a positively charged resin (an anion-exchange column) to bind a negatively charged protein and a negatively charged resin (a cation-exchange column) to bind a positively charged protein. Bind the protein to the column at low salt (e.g. 0.1 M NaCl) and elute with an increasing salt gradient. At some stage, the ionic attraction of the protein to the column resin will become weak enough to cause the protein to dissociate from the column and elute.

Tab. 1 The charge of the ionizable groups found on unmodified proteins as a function of pH.

Ionizable group	pK_a[a]	*pH 2*	*pH 7*	*pH 12*
C-terminal (COOH)	4.0	0 0 0 0 0	- -	
Aspartate (COOH)	4.5	0 0 0 0 0 0	- -	
Glutamate (COOH)	4.6	0 0 0 0 0 0	- -	
Histidine (imidazole)	6.2	+ + + + + + + + + +	0 0 0 0 0 0 0 0 0 0 0 0	
N-terminal (amino)	7.3	+ + + + + + + + + + +	0 0 0 0 0 0 0 0 0 0 0	
Cysteine (SH)	9.3	0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0	- - - - - - - - -	
Tyrosine (phenol)	10.1	0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0	- - - - - - -	
Lysine (amino)	10.4	+ + + + + + + + + + + + + + + + + +	0 0 0 0	
Arginine (guanido)	12.0	+ + + + + + + + + + + + + + + + + + + +	0	

[a] pK_a is the pH at which the ionizable group is half ionized. The precise pK_a value for a given ionizable group can be influenced by the immediate local environment.

3.4 Isoelectric Point

The isoelectric point (pI) is the pH at which the charge on a protein is zero and is determined by the number and titration curves of the positively and negatively charged amino acid residues on the protein. Protein pI values generally range from 4 to 10 (Fig. 1). An example of a theoretical titration curve and pI determination of *E. coli* RNA polymerase transcription factor, sigma32 (σ^{32}), is shown in Fig. 3.

3.5 Charge Distribution

The charged amino acid residues may be distributed uniformly on the surface of the protein or they may be clustered such that one region is highly positive while another region is highly negative. Such nonrandom charge distribution can be used to discriminate among proteins. An example is the *E. coli* σ^{32} protein (Fig. 3). At pH 7.9, σ^{32} has a negative charge of -46 and a positive charge of $+40$, giving a net charge of -6. It is able to bind reasonably tightly to both anion- and cation-exchange columns, apparently because its charged residues are not evenly distributed on the surface. This property can be used to purify this protein because most proteins will not bind to both types of ion-exchange columns under a single solvent condition.

3.6 Hydrophobicity

Most hydrophobic amino acid residues are buried on the inside of a protein, but some are found on the surface. The number and spatial distribution of hydrophobic amino acid residues present on the surface of the protein determine the ability of the protein to bind to hydrophobic column materials (as in hydrophobic interaction chromatography or HIC) and, therefore, can be exploited in fractionation. Generally, load a protein mixture onto a HIC column at high salt (e.g. 1 M ammonium sulfate), where hydrophobic interactions are strongest, and then elute with a decreasing salt gradient to successively elute more and more tightly bound proteins.

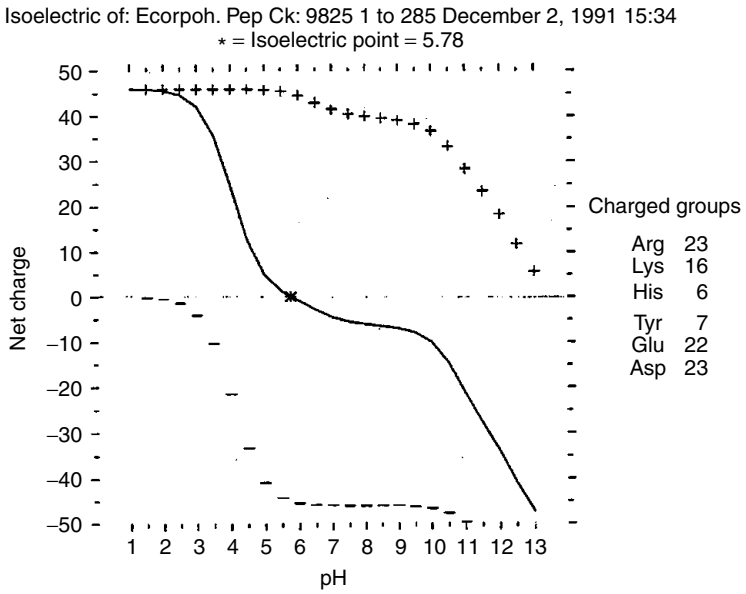

Fig. 3 Titration curve and isoelectric point (pI) of *E. coli* σ^{32}. This graph shows theoretical plots of the number of positively charged and negatively charged groups and the net charge as a function of pH for the *E. coli* RNA polymerase transcription factor σ^{32}, based on its amino acid sequence. The pI is indicated by the asterisk and is 5.78. The charged groups are Arg (23), Lys (16), His (6), Tyr (7), Glu (22), and Asp (23). This plot was generated using the Genetics Computer Group Sequence Analysis Software package.

3.7 Solubility

Proteins vary dramatically in their solubility in different solvents, all the way from being essentially insoluble ($<10\ \mu g\ mL^{-1}$) to being very soluble ($>300\ mg\ mL^{-1}$). Key variables that affect the solubility of a protein include pH, ionic strength, the nature of the ions, temperature, and the polarity of the solvent. Proteins are generally less soluble at their isoelectric point where there is less charge repulsion. Proteins are commonly fractionated by adding higher and higher concentrations of the mild salt, ammonium sulfate. Generally, the solubility of a given protein will decrease about 10-fold as the ammonium sulfate increases about 6% in saturation. (It takes about 760 gm of ammonium sulfate added to a liter of water to give a 100% saturated solution, which is about 4.1 M, at 20 °C). Since ammonium sulfate is mild and stabilizing to proteins, is relatively inexpensive and pure, and is highly soluble, it is the most common material used to fractionate proteins on the basis of solubility.

3.8 Density

The density of most proteins is between 1.3 and $1.4\ g\ cm^{-3}$ and this is not generally a useful property for fractionating proteins. However, proteins containing large amounts of phosphate (e.g. phosvitin, density = 1.8) or lipid

moieties (e.g. β-lipoprotein, density = 1.03) are substantially different in density compared with the average protein and may be separated from the bulk of proteins using density methods.

3.9 Ligand Binding

Many enzymes bind substrates, effector molecules, cofactors, or DNA sequences quite tightly. This binding affinity can be used to bind an enzyme to a column to which the appropriate ligand or DNA sequence has been immobilized. For example, the transcription factor AP-1 is purified by binding to a specific DNA affinity column.

3.10 Metal Binding

Many enzymes bind certain chelated metal ions (e.g. Cu^{++}, Zn^{++}, Ca^{++}, Co^{++}, and Ni^{++}) quite tightly, usually through interactions with cysteine or histidine residues. This binding can be used to bind an enzyme to a column to which the appropriate chelated metal ion has been immobilized. See Sect. 3.15 on the use of metal-chelate column for purification of protein tagged by the addition of 6 to 10 terminal histidines.

3.11 Reversible Association

Under certain solution conditions, some enzymes aggregate to form dimers, tetramers, and so on. For example, the ability of *E. coli* RNA polymerase to be a dimer under one condition (0.05 M NaCl) and a monomer under another condition (0.3 M NaCl) can be used if two fractionations based on size are carried out sequentially under those two different conditions.

3.12 Posttranslational Modifications

After protein synthesis, many proteins are modified by the addition of carbohydrates, acyl groups, phosphate groups, or a variety of other moieties. In many cases, these modifications provide handles that can be used in fractionation. For example, proteins containing carbohydrates on their surface can often be bound to columns containing plant lectins, which are molecules capable of binding tightly to certain carbohydrate moieties on glycoproteins. Phosphoproteins will in some cases bind to a chelated Fe^{++} column.

3.13 Specific Sequence or Structure

The precise geometric presentation of amino acid residues on the surface of a protein can be used as the basis of a separation procedure. For example, an antibody that recognizes only a particular site (epitope) on a protein can usually be obtained. An immunoaffinity column can be prepared by attaching a monospecific antibody (which binds only to the protein of interest) to a resin. Immunoaffinity chromatography (IAC) can result in highly selective separation and provides a very effective purification step. One can also immobilize a protein of interest and use it to specifically bind another protein out of a complex protein extract. This process is called *protein affinity chromatography*.

3.14 Unusual Properties

In addition to the types of properties mentioned above, certain proteins have unusual properties that can be exploited during their purification – an example is

unusual thermostability. Most proteins unfold and coagulate or precipitate when heated to 95 °C. A protein that remains soluble and active after such heat treatment can be separated easily from the bulk of the other cellular proteins. Another such property is unusual resistance to proteases. These two properties often go hand in hand. An interesting example of a purification involving these properties is that of *E. coli* alkaline phosphatase. The cellular extract is heated and the insoluble coagulated proteins are removed by centrifugation. The supernatant that contains the phosphatase is then treated with a protease, which digests the remaining contaminating proteins, leaving an essentially pure preparation of alkaline phosphatase.

3.15 Genetically Engineered Purification Handles

With the advent of genetic engineering, it has become relatively easy to clone the cDNA encoding a given protein. It is then possible to construct an overproducing strain of *E. coli* that can be induced to produce large amounts of a desired gene product. Recently, it has become common to alter the cDNA in such a way as to add a few extra amino acids on the amino terminus or the carboxyl terminus of the protein being expressed. This added "tag" can be used as an effective purification handle. One of the most popular tags is addition of 6 to 10 histidines onto the amino terminus of a protein. One then purifies the protein by its ability to bind tightly to a column containing chelated Ni^{++} or Co^{++} in which it can be washed and then eluted with free imidazole or by lowering the pH to 5.9, where histidine becomes fully protonated and no longer binds to chelated metal.

3.16 What Can Be Learnt from the Amino Acid Sequence of a Protein that is Useful in Purification?

These days it is very common to purify a protein in which the gene has been sequenced. Thus, one can easily deduce the amino acid sequence of the corresponding protein. Can this knowledge help in designing a purification scheme? The answer is that it can be somewhat, but not very, helpful. It is easy to determine the precise molecular weight of the polypeptide chain, but not to predict whether it forms dimers or tetramer or is part of a multisubunit complex. Its charge versus pH and its isoelectric point can be determined as shown in Fig. 3, which gives some idea as to which type of ion-exchange column to use, but again this will only be useful if it is not associated with other proteins. It is possible to calculate its extinction coefficient on the basis of its tryptophan and tyrosine content, which is very useful when it is pure. It is possible to determine if it has membrane-spanning regions or it has potential modification sites. One may be able to deduce that it is a member of a larger family of proteins by sequence alignment or by the presence of conserved sequence motifs that suggest cofactor affinity. However, its shape is not known, since the three-dimensional structure from sequence cannot yet be reliably predicted. Its multisubunit features cannot be predicted. Its ammonium sulfate precipitation properties cannot be predicted. Surface features such as hydrophobic patches, charge distribution, or antigenic sites cannot be predicted. Therefore, one must conclude that protein purification is still an empirical science.

4 Types of Separation Methods

There are a large number of separation processes that can be utilized to fractionate proteins on the basis of the properties listed above. These are summarized in Table 2. The sequential use of several of these separation processes will allow the progressive purification of almost any protein. If the processes are chosen carefully, and if proper attention is paid to separation conditions, and to maintaining the stability of the protein, the purification will result in reasonable efficiency, speed, yield, and purity, while retaining the biological activity and chemical integrity of the polypeptide.

An example of a hypothetical protein fractionation scheme is shown in Fig. 4. This scheme relies on three of the most common fractionation methods, ammonium sulfate precipitation, ion-exchange chromatography, and gel-filtration or size-exclusion chromatography. The purification summary in Table 3 is a typical way of summarizing the yield and specific activity of each of the major steps in a purification scheme.

5 Protein Inactivation and How to Prevent It

A protein purification scheme will generally not be considered successful if the result is a protein that is pure, but inactive. Therefore, one of the key considerations in working with a protein is to prevent it from becoming inactivated.

Tab. 2 Separation processes that can be utilized to fractionate proteins.

Separation process	***Basis of separation***
Precipitation	
Ammonium sulfate	Solubility
Acetone	Solubility
Polyethyleneimine	Charge, size
Isoelectric	Solubility, pI
Phase partitioning (e.g. with polyethylene glycol)	Solubility
Chromatography	
Ion exchange (IEX)	Charge, charge distribution
Hydrophobic interaction (HIC)	Hydrophobicity
Reverse-phase HPLC	Hydrophobicity, size
Affinity	Ligand-binding site
DNA affinity	DNA-binding site
Lectin affinity	Carbohydrate content and type
Immobilized metal affinity (IMAC)	Metal binding
Immunoaffinity (IAC)	Specific antigenic site
Chromatofocusing (CF)	pI
Gel filtration/size exclusion (SEC)	Size, shape
Electrophoresis	
Gel electrophoresis (PAGE)	Charge, size, shape
Isoelectric focusing (IEF)	pI
Centrifugation	Size, shape, density
Ultrafiltration	Size, shape

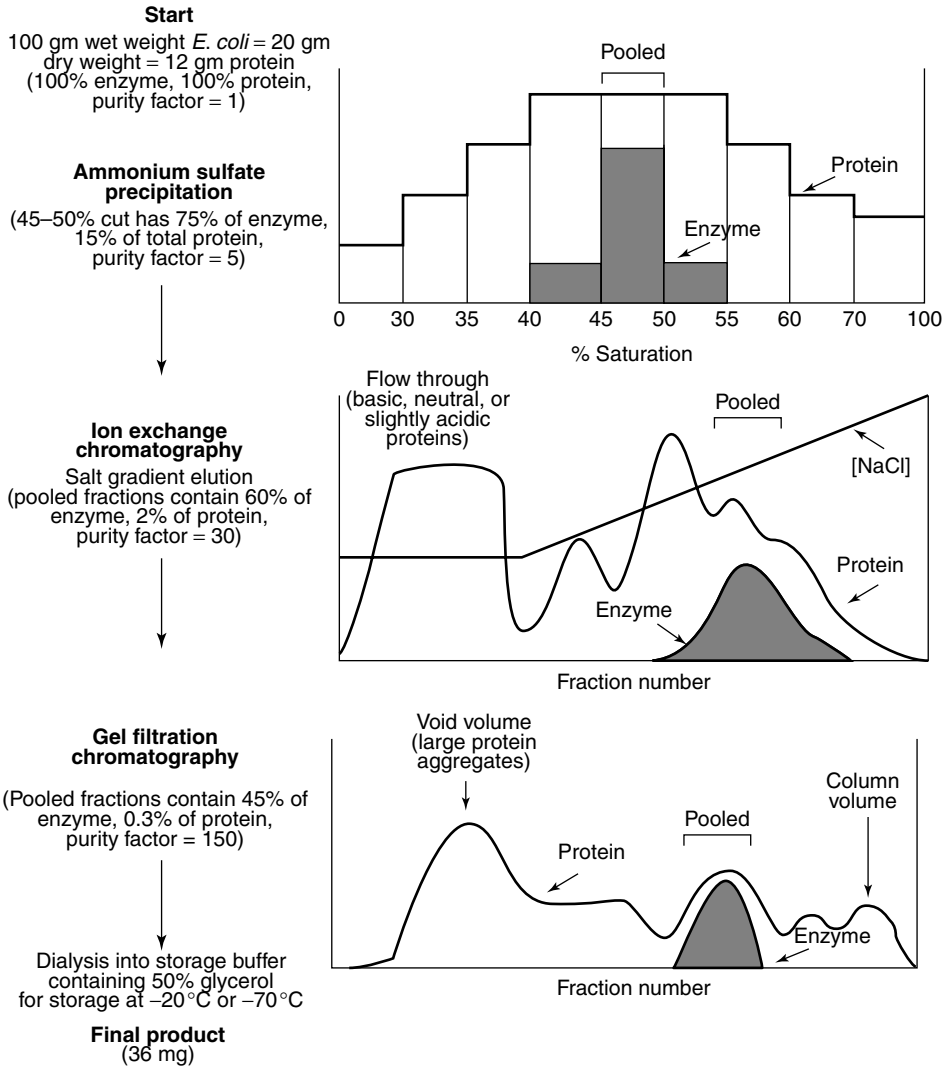

Fig. 4 A hypothetical purification scheme.

Table 4 summarizes some of the main reasons why a protein might become inactivated and what can be done to prevent this inactivation. In general, one works quickly and at low temperature (in a cold room or ice bucket) to avoid proteolytic degradation. One avoids foaming or undue exposure to oxygen and adds a reducing agent to prevent oxidation. One uses a buffer to maintain pH and a chelating agent like EDTA to protect against heavy-metal ions. Addition of 5% glycerol seems to stabilize most proteins and reduce adsorption to the walls of the container. A low salt concentration (e.g. 100 mM) helps increase solubility and prevent ionic adsorption to surfaces. Table 5 gives a good all-purpose buffer that in most

Tab. 3 Summary of hypothetical purification in Fig. 4.

Fraction	*Total Protein [mg]*	*Total Activity [%]*	*Specific Activity*	*Step Yield [%]*	*Overall Yield [%]*
Extract	12 000	100	=1		=100
				75	
AS pptn (45–50%)	1800	75	5		75
				80	
IEC (pooled peak)	240	60	30		60
				75	
Gel filtration (peak)	36	45	150 fold purification		45 final yield
Pure standard			150		

Tab. 4 Protein inactivation and ways of preventing it.

Reasons for inactivation	*How to prevent it*
Oxidation, foaming	Add DTT or TCEP, store under argon
Protease degradation	Add protease inhibitors, cooler, purer
Adsorption to container	Use polypropylene tubes, BSA carrier, glycerol nonionic detergent, protein more concentrated
Aggregation and precipitation	Store less concentrated, add salt, pH away from pI
Heavy metals	Add EDTA, cleaner tube, reagents
Temperature inactivation	Store cooler, add ligand or glycerol to stabilize
Bacterial growth	Use Tris, EDTA, azide, avoid PO_4, OAc^-
Enzymatic reaction (phosphatase)	Cooler, purer, add specific inhibitor
Dissociation of subunits/cofactors	Store more concentrated
pH changed	Avoid CO_2 in room, Tris changes pH with temperature
Inactive/misfolded conformation	Incubate at 37 °C to anneal the structure

Tab. 5 A good all-purpose buffer for keeping proteins happy.

TGED* + 0.1 *M NaCl

Buffer	50 mM Tris-HCl, pH 7.9 at 20 °C
Stabilizer	5% glycerol
Chelator	0.1 mM EDTA
Reducing agent	0.1 mM DTT (dithiothreitol)
Salt	0.1 M NaCl

Storage buffer – similar to above but has 50% glycerol. Will not freeze at −20 °C. Best stored at −70 °C.

cases will keep a protein active and happy.

6 Protein Purification Strategy

How one designs a purification scheme will, in large part, determine how successful one will be in achieving the goal of a protein purification: *that of getting a high yield of highly pure and active protein in the minimal number of steps*. Achieving a high final yield requires a high recovery at each step. Four steps at 80% step yield will be $(0.8)^4 = 0.41 = 41\%$ final yield, while 4 steps at 60% step yield will give a 13% final yield. Final purity will be guided by the intended use of the protein, but it should be free of major contaminants and any traces of enzymes that interfere with the intended use. High activity will depend on maintaining the stability of the protein as discussed in Sect. 5. By choosing high-resolution fractionation steps, one can achieve a given fold purification in fewer steps. For example, if the target protein is 0.01% of the total protein in the extract, it will require a 10^4-fold purification. This can be achieved in 4 steps, each giving a 10-fold purification, or 3 steps with a 22-fold purification, or 2 steps capable of 100-fold purification. The fewer the steps the faster the preparation, the lower the protein losses the lower the cost of the purification procedure. Some of the key considerations in designing a purification procedure are (1) to have a convenient assay to follow purification; (2) choose a starting material rich in protein; (3) take precautions to minimize damage, inactivation or loss; (4) use the minimal number of steps; (5) remove the bulk of material quickly; (6) avoid unnecessary duplication, dialysis, and delay; (7) generally use fractionation steps in the order: precipitation, ion exchange, affinity, sizing; and (8) use high-resolution steps where possible.

7 Overproducing Recombinant Proteins

The advent of genetic engineering has given us the ability to routinely clone genes and overproduce their gene products. This has changed the way we think about protein purification. For most protein purifications, one no longer starts with large amounts of naturally occurring material. Instead, clone the gene of interest, insert it into a suitable expression vector, transform the vector into a suitable expression host (e.g. *E. coli*), grow the cells, induce the transcription of the gene of interest, harvest the cells, break open the cells and purify the overproduced recombinant protein. By using an expression vector where the target gene has a strong, inducible promoter, it is possible to express the target to levels as high as 20 to 40% of the total cellular protein.

The most commonly used bacterial expression system was developed by Bill Studier and colleagues at Brookhaven National Laboratory, in the late 1980s. The host strain BL21(DE3) is a derivative of *E. coli* B that is deficient in several proteases to help prevent proteolysis of the recombinant protein and that has an inducible copy of the T7 phage RNA polymerase integrated as a phage lambda lysogen in the bacterial chromosome. The T7 RNA polymerase is kept repressed by the lactose operon repressor due to the placement of a lac operator near the promoter. The gene of interest is inserted into a multicopy expression vector under the control of a T7 RNA polymerase

promoter, also with a lac operator to keep it off. The vector also contains an extra copy of the lac repressor gene to enhance repression. The repressor and the presence of an additional plasmid (pLysS, that encodes a T7 lysozyme to inhibit low levels of T7 RNA polymerase activity) help keep uninduced transcription of the target gene low. When the cells have been grown to the desired cell density, the lac operon inducer, IPTG, is added to about 1 mM, causing the repressor to dissociate from the lac operators and allowing expression of the T7 RNA polymerase. The T7 RNA polymerase in turn actively transcribes the many copies of the plasmid-encoded recombinant gene and the resulting mRNA is efficiently translated into the protein of interest. The result can be the production of very large amounts of the recombinant protein, to as much as 20 to 40% of the total cell protein within about 4 h after induction. This means that it is possible to purify as much as 30 to 50 mg of recombinant protein from 1 gm of wet weight bacterial cell paste.

Several refinements have been introduced in the last few years to improve the chances that overproduction will be successful, especially if one is trying to overproduce a mammalian, plant, or archaeal protein. One problem is that human proteins often use codons that are rarely used in *E. coli*. These codons correspond to *E. coli* tRNAs that are very low in abundance in the cell. When one tries to overexpress a gene containing many of these rare codons, the result is that very little, if any, of the protein is produced. This problem was originally solved by changing the DNA sequence of the recombinant gene so that it did not contain rare codons, but it contained the preferred *E. coli* codons. A much easier and more elegant solution has now been developed and is marketed by several biotech research products companies. This involves creation of an improved host bacterial strain that has had 3 to 5 of its rare tRNAs augmented. Many poorly expressed proteins can now be expressed at very high levels. Table 6 lists this and several other problems that have been encountered in protein overexpression in *E. coli* along with how these problems have been solved or alleviated. There are a wide variety of elegantly engineered expression vectors and bacterial expression hosts available from many different biotechnology research

Tab. 6 Problems of poor recombinant protein expression and their solutions.

Problem	***Solution***
1. Target gene contains rare *E. coli* codons	Supplement host *E. coli* with rare tRNAs
2. Target mRNA is degraded	Use *E. coli* strain deficient in RNase E
3. Target protein is toxic to host cells	Use tighter repression, lower copy plasmid
4. Target protein is a membrane protein	Use a strain that has extra internal membranes
5. Target protein needs to form disulfide bonds	Use strain that is deficient in several key reductases, Gor, TrxB
6. Product normally forms stable heterodimers	Simultaneous coexpression of two different proteins in one *E. coli* strain

products companies worldwide. In addition to many *E. coli*-based expression hosts, there are also expression hosts such as: *Bacillus subtilis*, *Pichia pastoris*, *Aspergillus*, baculovirus/insect cells, mammalian cells, plants, and animals.

8
Refolding Proteins Solubilized from Inclusion Bodies

One of the most common problems in overexpressing a recombinant protein in *E. coli* is the fact that while large amounts of the protein are produced, most of it is not soluble, but is found as an insoluble inclusion body. Apparently, the newly synthesized protein, when partially folded into its native structure, exposes some hydrophobic regions and is quite sticky and prone to interaction with other partially folded proteins, leading to aggregation and inclusion body formation. There are two main approaches to dealing with inclusion bodies: (1) try to increase the proportion of the overproduced protein that is soluble; and (2) purify the inclusion body, solubilize it by dissolving it in a protein denaturant, and then refold it into its native structure.

8.1
Increasing Production of Soluble Protein

To purify the soluble material, one will want to increase as much as possible the proportion of the overproduced protein that is soluble. The most common approach is to induce the overproduction in cell growing at 20 to 25 °C. Apparently, the slower growth rate and lower temperatures results in more refolded protein and less aggregation and inclusion body formation. People have tried coexpressing cloned chaperone proteins to facilitate proper folding, but this is not common as it is only effective in some cases. An elegant recent approach, has been to grow the cells at 37 °C, shift the temperature briefly to 42 °C to induce the heat shock response, and then shift the cells to 20 °C for induction. Often if two proteins that normally form stable heterodimers are individually overexpressed they are insoluble, but if coexpressed in the same cell they form soluble, native heterodimers. Finally, many proteins remain soluble when overexpressed as genetic fusions with known proteins that readily fold to form stable native structures (protein fusion partners like NusA, GST, and TrxA).

8.2
Refolding Inclusion Bodies

If one chooses to refold protein solubilized from inclusion bodies, it is common to first wash the inclusion bodies with a nonionic detergent like TritonX-100 to solubilize membranes and break any unbroken cells. The washed inclusion body is then almost pure, and is ready to be solubilized. The real challenge is not the purification, but the refolding. The key to refolding without reaggregation and precipitation is to refold under low protein concentration. Under these conditions, the concentration of sticky, partially refolded material is lower, decreasing the opportunity for interaction and aggregation. However, for larger preparations, the large volumes become a major problem. Usually, one can find refolding conditions that give efficient refolding yields at reasonable protein concentrations.

8.3
A General Procedure for Refolding Proteins from Inclusion Bodies

A general method that the author has found to be quite effective for many proteins is given below.

a. Grow cells and induce overexpression of target protein.
b. Harvest cells, weigh cell pellet, store frozen at -80 °C
c. Break cells by sonication (pLysS cells are easy to break because of the presence of some T7 lysozyme). Otherwise adding lysozyme helps.
d. Centrifuge cell lysate, wash the IB pellet with 1% TritonX-100 to solubilize membranes and membrane proteins, then wash with buffer to remove TritonX-100.
e. Solubilize IB with a denaturant such as 6 M guanidium hydrochloride or 0.3% Sarkosyl to about 1 mg protein mL^{-1}. Difficult-to-refold proteins may need to be diluted to 0.1 mg mL^{-1} in denaturant; 8 M urea can also be used, but there is a risk of carbamylation of the protein.
f. Centrifuge out any undissolved material and slowly drip dilute the solubilized protein into 15 to 60 volumes of suitable refolding buffer. Additives or various buffer variables are often used to improve folding efficiency of a particular protein. These include 0.5 M arginine, 25% glycerol, varying the pH, temperature, presence of divalent ions, and presence of redox buffers.
g. Pass dilute refolded protein over a suitable high-resolution ion-exchange column, wash the column, and then elute with an increasing salt gradient. This step accomplishes several important things: (1) it concentrates the dilute protein; (2) it removes the denaturant; (3) it removes impurities that do not bind to the column or bind weaker or stronger than the target protein; and finally (4) it often separates refolded monomer from soluble multimers that tend to bind tighter and elute later in the gradient.
h. The resulting protein is usually fully active, homogeneous, and capable of forming crystals suitable for three-dimensional structure determination.

3 Summary and Conclusions – Evolutionary Principles 228

Bibliography 229
Books and Reviews 229
Primary Literature 230

Keywords

Alternative splicing
Creation of several different protein variants from one gene sequence using different exons.

Convergence
Independent invention of similar features.

Domain
A distinct (evolutionary) unit within a protein – can be defined from a structural, sequence-based, functional, or evolutionary perspective. Here, we concentrate on the structural and evolutionary domains.

Domain accretion
Tendency of eukaryote proteins to have more domains than their prokaryote homologs.

Domain architecture
The total number and type of domains within a protein and their relative orientations to one another.

Domain combination
Two or more structural domains that have combined at some time within a protein generally in tandem, though, domain insertions also exist.

Domain or protein family
Closely related sequences of domains or whole proteins.

Essential gene; essentiality
Gene with a lethal knockout phenotype.

Gene silencing
Upon a gene duplication event, the redundant gene copy is turned nonfunctional.

Homolog; homologous
Inferred evolutionary relationship.

Inserted domains
Protein domain A inserted into another domain B, so that B is interrupted in sequence.

Linker region; linker sequence
Amino acid sequence joining two domains.

Neo-functionalization
Emergence of novel protein function, usually after relaxation of selection upon a gene duplication event.

Nonsynonymous substitutions
Nucleotide substitutions that change the type of resulting amino acid.

Orphan (sequence)
Sequence without detectable homologs. Also called *singleton*.

Orthologue; orthologous
Homologs; homologous sequences related by descent, that is, speciation.

Paralogue; paralogous
Homologs; homologous sequences in one organism, related by gene duplication.

Protein Repertoire
The full complement of proteins encoded within an organism's genome.

Proteome
The fraction of the protein repertoire that is expressed in a particular organism or cell at a particular time.

Pseudogenes
Presumably untranscribed and untranslated, formerly active but now nonfunctional genes.

Sequence–structure–function Relationship
Relationship between the sequence, structure, and function of a protein. Protein evolution is marked by changes in these three characteristics at different rates.

Structural class
Top level of the hierarchical classification of protein domains. Groups domains according to their composition of alpha-helices and beta-strands.

Subfunctionalisation
Modification and divergence protein function, usually after relaxation of selection upon a gene duplication event.

Superfamily
One or more families of related domains or whole proteins.

Superfold
Notion of folds that are populated by many superfamilies.

Synonymous substitutions
Nucleotide substitutions that do not affect the type of resulting amino acid.

Transcriptome
The complete collection of transcribed elements from a genome.

Unifold
Notion of folds that comprise only one or very few superfamilies.

Abbreviations

aa: amino acid (residues)
BDIM: birth-death-innovation models
CATH: class(C), architecture(A), topology(T) and homologous superfamily (H)
DNA: deoxyribonucleic acid
3D: 3-dimensional
EC: enzyme commission
GO: gene ontology
HGT: horizontal gene transfer
HMM: hidden Markov model
NCBI: National Center for Biotechnology Information
NRDB: non-redundant database
NTP: nucleotide triphosphate
PDB: protein data bank
RMSD: root mean square deviation
RNA: ribonucleic acid
SCOP: structural classification of proteins
TIM: triose phosphate isomerase
WHD: winged helix domain

Proteins are the key players in our cells. Their entirety is what we call an organism's protein repertoire, encoded in its genome. Proteins are made up of smaller units called *domains*. Although single-domain proteins exist, the majority of proteins consist of at least two domains; the individual domains and nature of their interactions determine the function of the protein. Today, we have information on the sequence and structure of many proteins and domains. These data enable us to identify, describe, and compare the protein repertoires of a wide range of organisms and how they are determined by the tight interplay of sequence, structure, and function. The main evolutionary processes that form the protein repertoire are duplication, recombination, and divergence of the encoding sequences. Here, we describe these processes and how they affect protein structure and function. This allows us to draw general conclusions on the evolution of the protein repertoire on the organismal scale.

1 General Characteristics of the Protein Repertoire

Millions of different species inhabit our planet. One of the most fundamental problems in biology is to describe, organize, and understand the evolution of organisms that have very diverse characteristics. Although natural selection does not necessarily lead to an increase in complexity as organisms evolve, it is apparent that the complexity of certain lineages, such as our own, has increased during evolution.

The anatomy and physiology of an organism and its changes during evolution are determined primarily by its protein repertoire. The modularity of proteins, in turn, reveals the versatility of living organisms and their amazing ability to constantly evolve. One can imagine an increase in complexity by employment of three main mechanisms: (1) the invention of novel *modules*, for example, proteins or cells; (2) an increase in abundance of existing modules and their divergence; or (3) novel interactions between existing modules. The first of these mechanisms, *de novo* protein construction is relatively rare.

Here, we examine the protein repertoire, how it was formed via the duplication and recombination of existing modules, and how this contributed to the multitude of organisms that exist today. This provides, in contrast to single protein analyses, a much broader evolutionary insight into phylogenetic relationships. Understanding how the protein repertoire has evolved to produce functionally diverse and distinct proteins permits an appreciation of how speciation and evolution have occurred at a higher level.

1.1 Sequence, Structure, and Function

Proteins function as enzymes, regulators, messengers, or receptors; they form cellular structures, transporters, and storage devices. Proteins enable cells to grow, divide, and communicate with other cells or to respond to environmental input. They are found in cellular compartments or even outside the cell, attached to

the membrane or freely moving around. Proteins bind other molecules, such as DNA, RNA, lipids, metal ions, or carbohydrates, but they also interact with each other, forming large structures or functional complexes.

Proteins are characterized by the intimate relationship between their sequence, structure, and function (Fig. 1). Proteins of similar structure can have an enormous variety of functions, and an example of these are the TIM barrels. In contrast, the same function, for example binding to DNA, can be fulfilled by proteins of most different structures.

Similarly, the sequence and structure of a protein are intrinsically linked, and the chemistry of certain residues along with their surface location is responsible for maintaining the function of binding to the receptor protein. Even though apparently simple, understanding the relationships between these characteristics is crucial for an understanding of protein evolution. The amino acid sequence determines the structure a protein forms. Homologous proteins are of common evolutionary descent, and they often have similar sequences. Such sequence similarity is easy to detect and quantify with tools available today. However, protein structure is more conserved than sequence, and, frequently, the structure of related proteins will be similar despite the sequences having greatly diverged from one another.

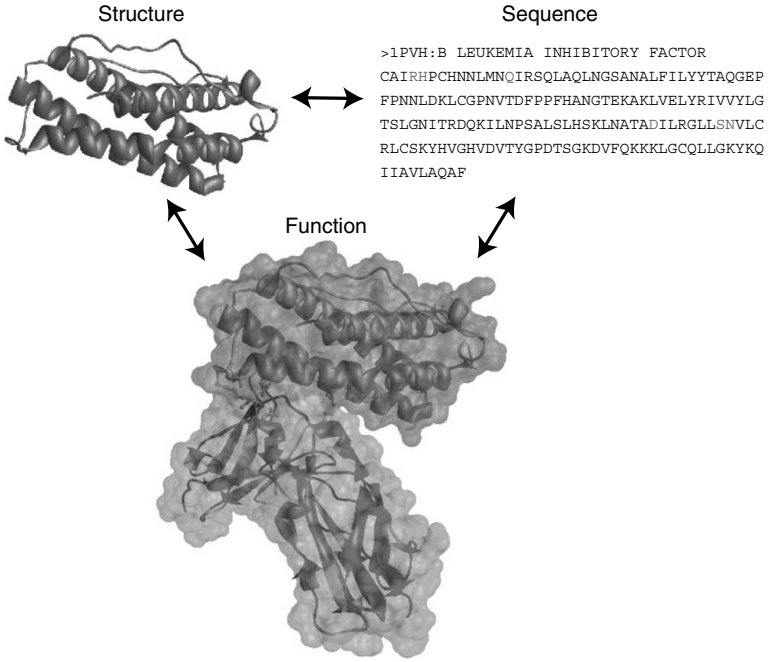

Fig. 1 Proteins are characterized by their sequence, structure, and function. The sequence, individual domain structure (colored purple), and interacting structure (with Gp130 colored blue) of leukemia inhibitory factor are shown (Protein Data Bank (PDB) ID: 1pvh). Within the sequence and interacting domains residues that are colored red form hydrogen bonds with the receptor. (See color plate p. xxxiii.)

In the triangular relationship between sequence, structure, and function (Fig. 1), small changes at the level of the sequence can produce either large or small changes in the structure, which, depending on location, may impact the protein's function. A single nucleotide substitution can produce an amino acid change, which might alter specificity or binding affinity. A classic example of this is the discovery of sickle cell anemia by Vernon Ingram in 1956, the first disease that was documented on a molecular level. Ingram showed that the replacement of glutamic acid by valine at position 6 in hemoglobin β-chain was responsible for the abnormality. This substitution produces alterations in the structure such that haem binding and thus iron transport is compromised, resulting in sickle cell–shaped red blood cells and serious anemia.

In the following sections, we describe some aspects of the sequence, structure, and function of proteins and how they relate to each other.

1.2 Related Proteins Form Families

In order to understand the protein repertoire and how it evolves, we need to know the evolutionary or phylogenetic relationships between the proteins. Margaret Dayhoff was amongst the first to introduce the notion that proteins can be grouped into *families* and *superfamilies* of related molecules and recognized the role of these relationships in protein evolution. These concepts of families and superfamilies have played heavily into construction of our present-day classifications of proteins.

A family was defined as a group of related sequences based on sequence similarity. The evolutionary relationship is obvious from the amino acid sequence alone: if two sequences are highly similar, the proteins are likely to be related. Many methods exist to detect these sequence similarities today, for example, BLAST. As we commented on earlier, the structure of two related proteins can be remarkably similar despite their sequence having diverged beyond recognizable similarity. In superfamilies, which can comprise one or more related families, sequence similarity is often undetectable, and the evolutionary relationship is demonstrated by structural and functional information.

A wonderful example of related proteins with minimal or no sequence similarity is the four-helical cytokine superfamily. These proteins are known to bind to receptors and trigger signaling cascades functioning in immune and circulatory systems. Distinctive structural features reveal, however, that four-helical cytokines can be subdivided into three different families: the interferons that have a fifth helix, the short chain cytokines that have a small two-stranded beta-sheet and subtle folding differences, and finally the long-chain cytokines, which have longer chains. The structure-based family classification was confirmed by analysis of the gene structure, which showed remarkable conservation of intron/exon structure with respect to the secondary structure elements.

1.3 Most Proteins Fold into Structures

Most proteins fold into very distinct three-dimensional globular structures. Protein structures solved by X-ray crystallography or NMR are deposited into the protein data bank (PDB), a central repository for all proteins of known structure. At a basic level, we distinguish alpha-helices, beta-strands that fold into sheets, turns,

and loops, as structural elements. These elements are connected to form simple motifs. These structural motifs fold into domains. Polypeptide chains or proteins can consist of several such domains.

A small set of proteins are fibrous proteins that often play structural roles in, for example, keratin in hair. In addition, a significant fraction of proteins do not fold into distinct structures and form so-called *unstructured* or *disordered* proteins. Often, this group of disordered proteins is overlooked when considering the protein repertoire. Machine learning neural network predictors trained to detect regions of sequence that are likely to be disordered predicted that 35 to 51% of eukaryote proteins have at least one disordered region of >50 residues, and that fully disordered proteins correspond to 11% of proteins in Swiss-Prot and 6 to 17% of proteins in various genomes. At this time, most of our protein evolution knowledge is derived from globular proteins – and it is unclear how similar the evolution of unstructured proteins is.

1.4 Domains are the Units of Protein Evolution

We now discuss one of the key concepts for studying the protein repertoire – that of protein *domains*, that is, the structural and functional units that make proteins

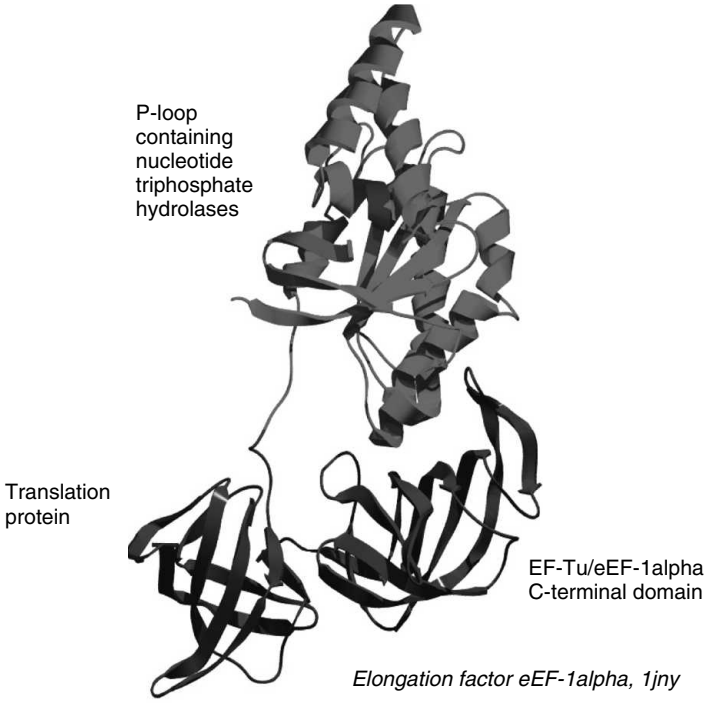

Fig. 2 Domains are the units that make proteins. The eukaryote elongation factor eEF 1-alpha is a beautiful example of a protein that is structured into domains: the P-loop hydrolase domain hydrolases GTP and thus triggers conformational change, the Translation protein domain interacts with the ribosome (not shown) in order to prolong translation.

(Fig. 2). We also discuss the definitions, classification schemes, and properties of domains, and explain how domains allow us to understand protein properties and the evolution of proteins.

The concept of protein domains arose when the first X-ray structures of proteins were determined. These structures, for example, globin or insulin, appeared to be single compact entities. Other protein structures seemed to contain several of these compact entities, and this suggested that proteins are divided into distinct structural units that fold independently, analogous to beads on a string. Typically, domains are regions of compact protein structure with a hydrophobic core. Levitt and Chothia were the first to classify the arrangements of secondary structure elements in a set of proteins available at that time. These representations led to the identification of four distinct protein classes: all-alpha, all-beta, alpha + beta and alpha/beta – these remain the main classes used today.

In 1974, Rossmann et al. realized that domains represented *evolutionary* rather than only structural units. They observed that several nucleotide-binding domains displayed structural similarity, and they speculated that these domains had descended from a domain present in an ancestral protein. Importantly, they also recognized the value of structural information for these analyses: only ''a combination of structure and sequence permits a measurement of more distant evolutionary relationships''. Later, Murzin et al. constructed the structural classification of proteins database (SCOP), which uses such an evolutionary domain definition (Fig. 3). In SCOP, a structural unit within a protein only qualifies as a domain if it is observed in isolation as a single-domain protein and/or in different combinations with other structural units. Evidence for the evolutionary relationship between domains is taken from detailed examination of protein structure, and, additionally, sequence and function.

Alternative views on domains include the idea that fold space consists of repeated small structural motifs, such as helix-turn-helix motifs, smaller than the compact entities considered domains in other structural approaches. Certainly, folds such as TIM-barrels and other barrel type structures consist of the same small structural motif repeated several times. It is easy to imagine how duplication and assembly of the smaller motifs might lead to the evolution of these larger protein domains. Indeed, some protein fragment matching and assembly-based approaches have been very successful recently when applied to the *ab initio* protein fold prediction problem.

Protein domains are of great diversity, and today there are many databases using their own domain definitions and different protein classifications. The definition of a protein domain remains complicated and can be approached from a structural, sequential, or functional perspective. For answering evolutionary questions, however, it is crucial to define a domain in an evolutionary context – and this is why we use the term *domain* always with reference to the evolutionary unit defined in SCOP.

1.4.1 Evolutionary Hierarchical Domain Classification (SCOP)

SCOP is a completely manual classification for proteins of known structures and is considered by many as the gold-standard classification. The hierarchical classification starts at the level of individual domains or small proteins (Fig. 3). A SCOP domain typically has 100 to 250 amino acid residues, though smaller and

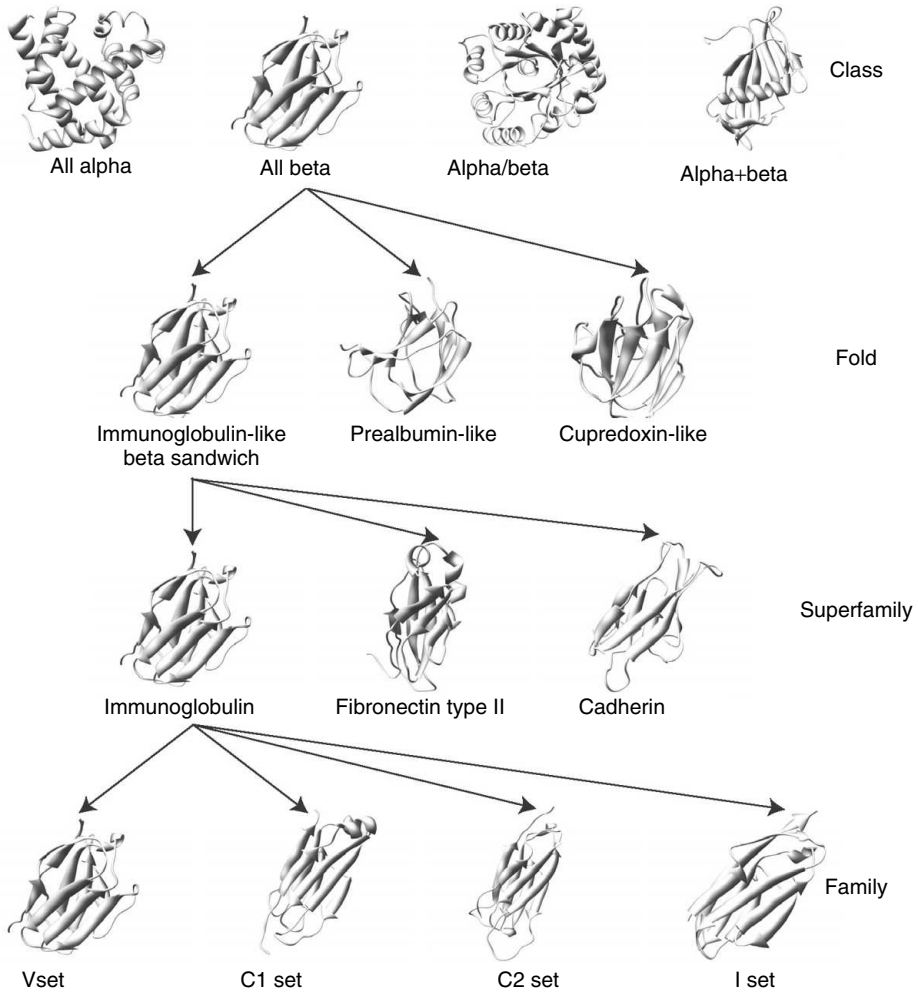

Fig. 3 The SCOP classification. The hierarchical classification is illustrated by the example of the Immunoglobulin domains. One representative structure is given at every level – note that not all folds are shown for this class, and not all superfamilies for this specific fold.

larger domains do occur. Closely related domains are then grouped into families on the basis of having a common evolutionary ancestor evidenced by structural similarity and more than 30% sequence identity. Superfamilies at the next level are made up of families for which the structure and function suggest a common evolutionary relationship, but which have sequence identities below 30%.

The subsequent level of classification is the fold. Superfamilies and families of domains of the same fold have equivalent major secondary structure elements in a similar arrangement with the same topological connections. Superfamilies within the same fold have an unresolved relationship and may be convergently or divergently related – but for which we are currently lacking information either way.

The final level of SCOP is class, which comprises the original all-alpha, all-beta, alpha/beta (a/b), alpha + beta (a + b), and seven additional, smaller classes.

Note that in the literature, the expressions *fold*, *family*, and *superfamily* are often used with different and overlapping meanings and the hierarchical levels are then blurred. For example, fold is sometimes used to describe superfamilies or even single structures; or protein families are not grouped into superfamilies. There are many potential additional relationships between proteins for which we lack evidence as yet, for example, between superfamilies of the same fold. As more protein structures and sequences become available and our methods advance, some of these relationships will be clarified and classifications updated.

1.4.2 Alternative Domain Classifications

In addition to the evolutionary domain definition used in SCOP, there are many other systems of domain classification and they use a variety of definitions and methods. Some databases center their classification completely on structure, others on sequence similarity; the classification can be done manually, completely automatically, or using a combination of both approaches. Some so-called *metasite*s, for example, Interpro, combine the output of several different databases.

An alternative and also commonly used protein structural database is the classification architecture topology and homology (CATH) database. CATH uses structural criteria and a domain definition similar to the one used in SCOP. It classifies domains into homologous superfamilies, topologies, architectures, and classes using a combination of manual and automated methods. The main automated approach to domain definition is to identify segments of protein structure with more internal contacts than contacts to other regions of the structure. Additionally, there are many other structural domain classifications, for example, the families of structurally similar proteins (FSSP) or the molecular modeling database (MMDB), both of which are fully automated.

In both SCOP and CATH, the top levels of the hierarchy are defined by the three-dimensional structure, whereas lower levels are identified by sequence similarity. There is an extensive agreement of the classification of the proteins in both databases, although some exact criteria on topological similarity have yet to be determined. There are, however, some striking differences between the domain definitions of these two resources. One such example is that of protein kinases, which are classified as one single domain in SCOP, but is split into two domains in CATH (Fig. 4). In favor of the CATH definition, there are two distinct lobes within the kinase domain. These two lobes, however, are only ever found together and bind ATP at their interface, and this strongly supports the SCOP single-domain definition of kinases as an individual evolutionary domain. Such classifications are to some extent subjective – it is important to remember that alternatives exist and should be used according to the precise context and what question is being looked into.

Some databases rely on sequence rather than structural similarity for clustering domains into families. Examples of these databases are Pfam and SMART, both of which use HMMs as a basis for the alignments they provide. Other databases rely completely on the conservation of sequence stretches in multiple alignments, such as the ones used for TRIBE-MCL or ProtoMap.

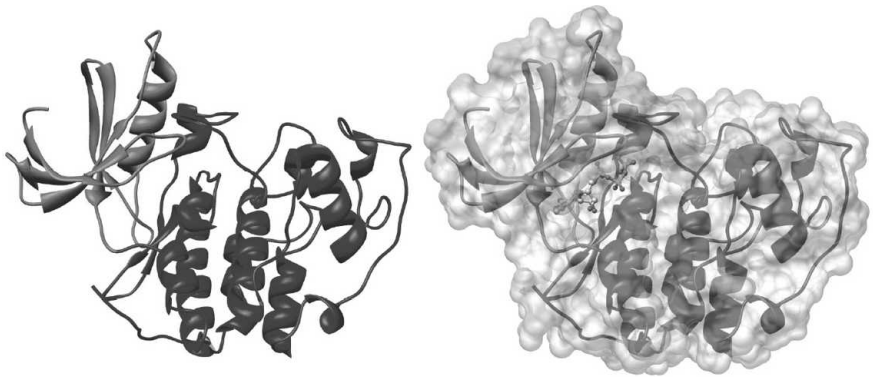

Fig. 4 Protein kinases, as defined in SCOP and CATH. On the left is the kinase domain (PDB ID: 1hck) colored according to the CATH definition of two distinct structural domains (first CATH domain residues 1–84 red, the second CATH domain residues 85–297 blue). On the right, the same coloring is implemented; however, we also show the surface of the entire kinase domain and the location of the bound ATP. This highlights the fact that in terms of surface the entire domain appears as one globular structure, and the location of the ATP binds at the interface of the two CATH defined domains. Functionally, both domains are necessary for ATP to bind and therefore the single-domain SCOP definition seems more accurate in terms of functional, evolutionary domain definition. (See color plate p. xxxiv.)

Sequence-based domain definitions have the advantage that domains of as yet unknown structure and unstructured regions can be included. Homology from sequence similarity, when present, is easier to detect than from structural similarity. We are positive that when significant similarity exists between two sequences, domains are homologous. However, in order to detect all remote relationships, sequence similarity alone is often insufficient and thus it is only of limited use for answering evolutionary questions. In such cases, other conservation of other structural features should be included for consideration. Structure and its finer details, for example, alpha-helix caps, beta-bulges, conserved turns and so on, is a potentially better tool for understanding evolution of the protein repertoire. Currently, such approaches are limited to mostly manual analyses, and we need to develop more automated tools to render their use possible on a genome-wide scale.

1.4.3 Implications and Complications of Domain Definitions

The evolutionary domain definition in SCOP and the knowledge inherent within this classification on the relationships between proteins have important implications. We discuss some of these below.

Firstly, information about the evolutionary relationships between domains is most useful to identify homologous proteins in different genomes. When we find domains of the same superfamily in two different proteins, we know that these proteins, or at least parts of them, are related by descent. The proteins must have arisen by duplication and recombination of the ancestral sequence.

Secondly, the exact definition of a domain in terms of its start and end location within the protein sequence is sometimes complicated. The domains can be joined by long *linker* regions, which sometimes fold into secondary structure elements. Many domains can also have

long insertions in the form of loops, alpha helices, or other elements. In the extreme case, whole domains, called *inserted domains*, can be introduced into the middle of another domain, interrupting the sequence contiguity. Thus, despite all efforts to consistently classify protein structures, many exceptions or special cases have to be considered.

Finally, it remains a matter of debate whether individual folds (structural topologies) arose only once during evolution or whether some of them arose by *convergence* from unrelated ancestors. The basic physicochemical interactions and associated structural and sequence motifs are often conserved across different superfamilies within one fold. In contrast, the same activity and/or function can be performed by two or more completely unrelated structures. Anecdotal cases of *convergent* evolution have been reported in the literature where there is currently no evidence of the proteins being derived from a common ancestor. A well-known example are serine proteases: chymotrypsin and subtilisin are members of two different superfamilies, but the three-dimensional arrangement of the catalytic residues and the reaction mechanism are the same. Another example is MutS and topoisomerise II, which share a structural motif that in its dimeric form is suitable for sensing DNA topology and binding recombination intermediates. Such examples might prove wrong once our ability to detect remote homology improves. When we do not have sufficient evidence of different origins of two protein folds, the relationship is really unresolved in terms of evolution rather than a definite case of convergent evolution. This general lack of proof for convergent evolution led to the suggested use of the term *parallel* rather than convergent evolution.

There is, however, very little doubt that domains with clear structure, sequence, and/or functional evidence of homology have one common ancestor, even in the absence of detectable sequence identity. While classification systems such as CATH contain some information on domain homology, to the best of our knowledge, SCOP is the only one, which defines domains from a more hierarchical evolutionary perspective and incorporates several homology levels. Thus, the evolutionary domain definition in SCOP provides the basis for many exciting analyses into the evolution of the protein repertoire. We can examine the changes in structure across homologous proteins, and how this is linked to changes in sequence and function. We can also compare orthologous proteins in different organisms and try and understand how they may contribute to organism-specific features. Finally, knowledge of the relationships between proteins can help method development, such as to establish evaluation procedures for homology recognition algorithms.

1.4.4 Domain Prediction

In order to study the protein repertoire, for example, the number, distribution, or sizes of domain families in different organisms, we need as comprehensive as possible knowledge on the presence or absence of particular domains in those organisms. While we currently know the structure of more than 25 000 proteins, this covers only a small fraction of all proteins in a particular organism. We can increase this coverage by predicting domains and their structures. This is done by inference, that is, exploiting homology with proteins of known structure, or *ab initio*, that is, prediction of the structure of proteins with new folds.

Many classification systems mentioned above include algorithms to predict domains based on sequence and/or structural homology. Today, we have the complete genome sequence for more than 130 organisms, and, for example, with the use of the SUPERFAMILY database, it is possible to make domain predictions for 40% of eukaryote sequences by inferring homology from sequence similarity – and these are the data that we discuss here. Despite some apparent biases in the proteins of known structure, for example, more globular and soluble proteins, and overrepresentation of some proteins of high biological interest, for example, immunoglobulins and globins, we assume that the conclusions drawn from this partial information are still of general relevance and depict a more refined picture of the protein repertoires than that which was previously known – and this picture will continue to be polished as more data becomes available.

1.5 How Many Different Families, Superfamilies, and Folds Exist in Nature?

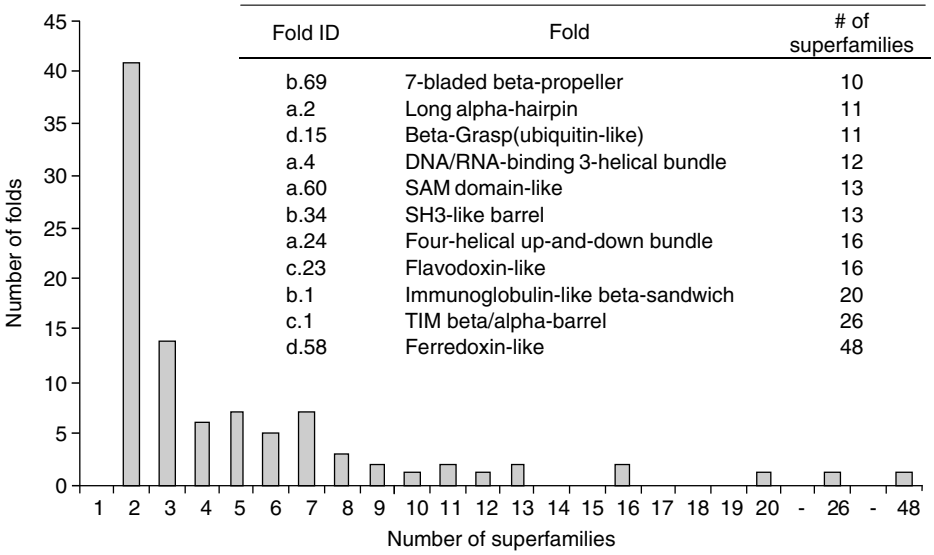
The first important question that may arise, after consideration of appropriate domain definition and classification, is on the size of the protein universe, that is, how many different families actually exist in nature and how many novel families are yet to be discovered.

There are more than 1200 domain superfamilies in the current version of the SCOP database, and it is likely that these cover the most common superfamilies. Estimates on the total number of folds or superfamilies, however, vary – partly due to the blurred definitions of fold and superfamily. Early speculation about the total number of protein families and superfamilies relied largely on the rate of discovery of new families, and they predicted around 1000 common superfamilies. When other assumptions or methods were used, the estimates of the total number of existing families, superfamilies, or folds vary from a few hundred to several thousand.

In some respect, the exact number of domain superfamilies might be of little importance, since the distribution of the number of proteins per superfamily or the number of superfamilies per fold is extremely uneven: a few folds are very popular and have many superfamilies. These superfamilies, in turn, also occur in many different proteins (Fig. 5). These folds are also called *superfolds*. Superfolds often have very generic functions and contain structures such as the P-loop NTP hydrolases, Rossmann folds or TIM barrels. In contrast, the majority of novel folds that have been discovered recently tend to only have a small number of superfamily members. They are also known as*unifolds*; it remains unclear how many of the unifolds encompass the still unknown proportion of the protein repertoire.

1.6 The Distribution of Protein and Domain Families Across Different Genomes

Once we have an idea of the number of different domain families that exist in nature, we might like to know how they are distributed across different species. We obtain a first and simple measure of similarity between organisms, how they are related and evolved, and how the organisms' complexity is determined by, for example, the number of different domain superfamilies that occur, their kind, and size.



Fold ID	Fold	# of superfamilies
b.69	7-bladed beta-propeller	10
a.2	Long alpha-hairpin	11
d.15	Beta-Grasp(ubiquitin-like)	11
a.4	DNA/RNA-binding 3-helical bundle	12
a.60	SAM domain-like	13
b.34	SH3-like barrel	13
a.24	Four-helical up-and-down bundle	16
c.23	Flavodoxin-like	16
b.1	Immunoglobulin-like beta-sandwich	20
c.1	TIM beta/alpha-barrel	26
d.58	Ferredoxin-like	48

Fig. 5 Distribution of the number of superfamilies within folds in SCOP 1.65. The inset table provides details of the super- or hyper-folds with 10+ superfamilies. There are 602 folds, which have only one superfamily – this is not shown as a bar on the histogram.

Early studies provided a census of genomes in terms of structures, highlighting differences in preferences for secondary structures and folds. Some studies suggest that globular domains occurred early in evolution, with the alpha/beta class being possibly the first.

Later, these analyses were tailored to the distribution of domain families and superfamilies; and again, any conclusions we draw are from those 40% of the sequences to which one or more domains are assigned. For example, in most metazoans, we find about 800 different domain superfamilies out of a total of about 1200 known superfamilies, whereas the unicellular baker's yeast and bacteria have about 650 or even fewer (Fig. 6). Some superfamilies are conserved across different genomes; and the more closely related are two genomes, the larger the fraction of conserved superfamilies. For example, around 400 superfamilies or 35% occur in 14 eukaryote organisms including yeast, invertebrates, and vertebrates. The members of these superfamilies form up to 90% of the domains in these organisms, which makes the protein repertoires between these organisms very similar in terms of domain composition. In contrast, only about 20% of the domain superfamilies or even less occur in all three kingdoms of life. These 20% of all superfamilies comprise, however, around 80% of all domains.

This means that most of the superfamilies evolved long before the split of eukaryotic clades. Sequences encoding domains of these superfamilies have subsequently been duplicated many times and are modified and reused in many different contexts; and we discuss these mechanisms – duplication, modification, and reuse – later in more detail.

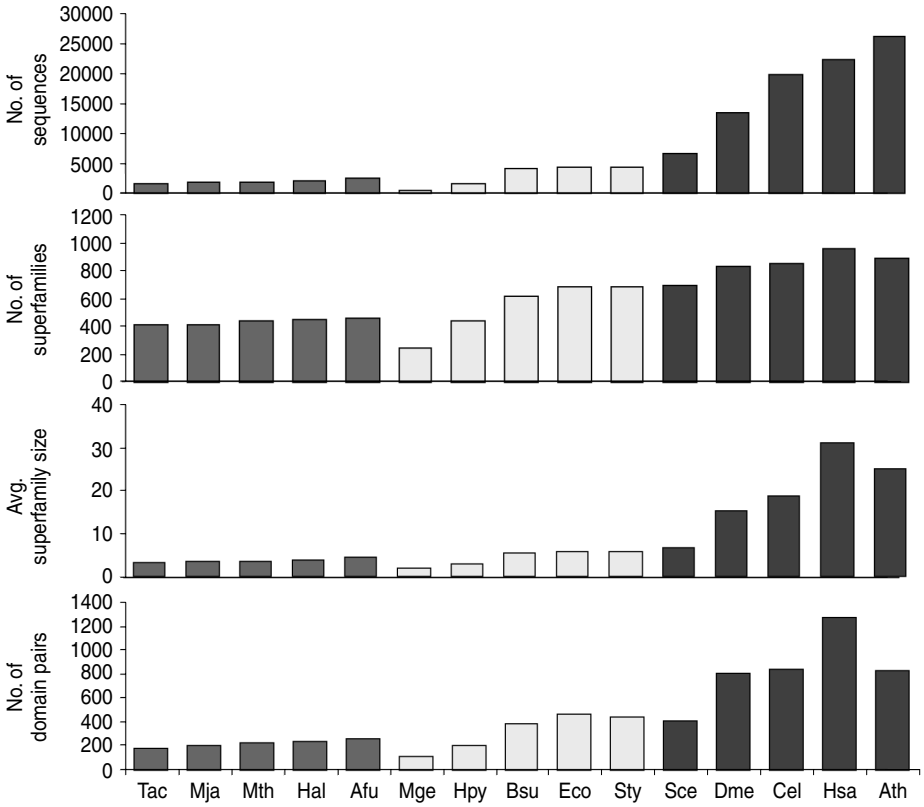


Fig. 6 Different features of the genome and protein repertoire. From top: The total number of sequences (genes) predicted for each organism. The total number of different SCOP domain superfamilies predicted with SUPERFAMILY version 1.65 (http://supfam.mrc-lmb.cam.ac.uk/SUPERFAMILY/). The average number of proteins per domain superfamily that is, number of duplicates per domain superfamily. Finally, the number of different two-domain combinations. Red – Archaea: Tac, *Thermoplasma acidophilum*; Mja, *Methanocaldococcus jannaschii*; Mth, *Methanothermobacter thermautotrophicus* Delta H; Hal, *Halobacterium* sp. NRC-1; Afu, *Archaeoglobus fulgidus* DSM 4304. Yellow – Bacteria: Mge, *Mycoplasma genitalium*; Hpy, *Helicobacter pylori* 26695; Bsu, *Bacillus subtilis* ssp. subtilis 168; Eco, *Escherichia coli* K12; Sty, *Salmonella typhimurium* LT2. Blue – Eukarya: Sce, *Saccharomyces cerevisiae*; Dme, *Drosophila melanogaster* 3.2; Cel, *Caenorhabditis elegans* WS123; Hsa, *Homo sapiens* 22.34d; Ath, *Arabidopsis thaliana* 5. (See color plate p. xxxv.)

1.7 Proteins Interact

Proteins interact – they are part of complexes, cellular structures, and pathways. Many *stable* protein complexes are crucial for the cell to work: the transcription factor assembly, the splicing machinery. *Transient* interactions of proteins or protein domains have important roles, for example, in signaling cascades or cell cycle regulation. These interactions are part of protein function and hence constrain the evolution of sequence. Indeed, proteins

in stable complexes are more conserved than proteins in transient complexes, and, generally, the more interaction partners a protein has, the slower it evolves. Proteins with many interaction partners tend to have well-conserved sequences and frequently have essential functions. Domains within proteins also interact, and we discuss the details of their spatial arrangement in a later section.

Recent years have produced an enormous growth of genome-scale protein interaction data and revealed that, similar to other biological phenomena, protein interaction networks are of a scale-free nature. The hubs in these networks, i.e., proteins with many interaction partners, are either part of stable complexes or are involved in crucial transient interactions mentioned above. With a map of protein interactions, we can better understand the evolution of the protein repertoire with reference to the constraints placed by interactions and the resulting functions.

1.8 Proteins are Part of Pathways

Many proteins, for example enzymes or signaling molecules, are part of pathways, such as in metabolism or signal transduction. In the *Escherichia coli* small-molecular metabolism, about 600 proteins act in about 100 pathways, and one-quarter of the enzymes are involved in multiple pathways. Even this basic set of ancient enzymes seems to have evolved by means of extensive duplication and recombination.

Whether the function of a single protein, or of the entire pathway, is essential decides whether the organism will survive in case of a mutation and thus influences the rate of evolution of the protein. Again, we see many biases: most domain superfamilies occur in only a few pathways, whereas a few domain superfamilies of very generic function occur in many pathways.

The ''Horowitz'' model assumes that duplicated enzymes tend to be employed in the same pathway so that enzymes in consecutive reaction steps are often homologous. However, despite extensive domain and protein duplication across metabolic enzymes, this is only partially true. For most of the homologous proteins, the catalytic mechanism or cofactor-binding properties are conserved or only slightly modified while the substrate specificity has changed. This suggests that it is much easier to evolve new binding sites than new catalytic mechanisms. Thus, the recruitment of homologous domains in novel pathways primarily occurred on the basis of catalytic mechanism or cofactor binding, and this speaks against the Horowitz model.

The network of biological pathways is amazingly robust. More than half of all genes in yeast have, when knocked out, no, or hardly any, apparent effect on the fitness of the organism, that is, they are nonessential. Many of these genes might, however, be of important function under nonhomeostatic conditions such as when subject to stress. The apparent robustness is not only due to the functional redundancy created by the many duplicate genes but also by alternative routes to producing the same molecules.

The same pathway in different organisms can contain species-specific sets of isozymes. Enzymes responsible for the same reaction in the same pathway but in different organisms can also be completely unrelated. This phenomenon is called *nonorthologous* replacement, and one example is lysyl-tRNA-synthetases, which occurs in two unrelated protein families across bacteria and archaea.

The recruitment of single enzymes from different pathways could be the driving force for pathway evolution, and some enzyme families are capable of changing both reaction and substrate chemistry. Such recruitment seems more prevalent than, for example, whole pathway duplication, enzyme specialization, *de novo* invention of pathways, or retroevolution of pathways. Together, these variations produce ''mosaic'' network of pathways in different organisms with a widespread plasticity.

1.9 Protein and Domain Function

The function of a protein is usually determined by the interplay of its sequence and three-dimensional structure. However, two proteins of very similar functions may have arisen from different ancestor molecules and/or can have different structures. A well-documented example of functional convergence is the Ser/His/Asp catalytic triad of the serine proteases found in several different protein folds. The converse is also true: proteins that are structurally or evolutionarily related do not necessarily have identical functions such as is seen for the large TIM-barrel fold.

Similar to structure classification, the identification and useful classification of protein function is nontrivial. Several classification schemes for protein function have been developed in recent years, and it is important to choose the scheme according to the question that is to be addressed. Each scheme has its own advantages and disadvantages. One of the oldest systems is that of EC-numbers, classifying chemical reactions of enzymes.

A more recent classification, that comprises both enzymes and nonenzyme proteins, is gene ontology (GO) which classifies protein subcellular localization, molecular function, or the biological process of proteins in three separate ontologies. The distinction between the molecular function of a protein and the biological process in which it acts is very important, and, to the best of our knowledge, GO is the only classification system thus far that makes it. For example, a kinase's molecular function is to transfer phosphate groups. Kinases can, however, also act in processes as different as signal transduction, glycolysis, or muscle movement. A disadvantage or difficulty in GO is its nonhierarchical character and that the depth of description is inconsistent at various levels of the graph.

1.9.1 Indirect Function Characteristics

The function of a protein is tightly coupled to its sequence and structure, but also to many other characteristics, such as its interaction partners, its localization in the cell, position in the genome, and so on. These characteristics co-evolve and, thus, they can be used to predict protein function and to study function evolution.

Firstly, function prediction often relies on sequence similarity, assuming that homologous proteins have related functions. The predictions are reliable if the sequence identity to a homolog of known function is greater than about 40%. If the sequence identity is low, the three-dimensional structure of the protein might still give clues as to the function, but the situation is much less clear.

Secondly, proteins of similar function tend to co-localize on the genome. In prokaryotes, genes that participate in the same process tend to be organized in an operon; but a nonrandom gene order is also observed in eukaryotes. Housekeeping genes, for example, tend to form clusters on the chromosome.

Thirdly, proteins of the same pathway tend to interact. Fourth, a functional link between two proteins is assumed to encourage the physical fusion of the two genes, and this approach has been termed *Rosetta Stone principle*. In the fifth place, two functionally linked proteins also tend to show the same phylogenetic profile. That means two genes that show the same pattern of presence or absence in a number of organisms tend to be functionally linked. Penultimately, functionally related proteins are often co-regulated in the same subcellular compartment or have similar effects on the knockout phenotype.

Last but not least, the existence of the same domains in two proteins, for example, two enzymes from different organisms, and their interactions with other domains can also tell us whether these enzymes carry out a similar function. Thus, the domain composition can be used to predict protein function or localization.

1.9.2 Functional Annotation of Domains

The function annotation of protein domains is even more difficult. GeneOntology annotation is available for some Pfam domains, but only a few hundred of them have equivalents to SCOP domain superfamilies. It is, however, difficult to use a whole-gene-based annotation scheme, such as GO, for domains. Most proteins consist of several domains, which can have different functions. For example, a kinase domain can be found with a lipid-binding and/or protein interaction domain. Such considerations made it necessary to develop a novel domain-based annotation scheme, and Bashton and Chothia have done so. Their scheme is domain-centric and emphasizes domain function in the context of domain neighbors in multidomain proteins, providing functional annotations for a subset of SCOP domains. The annotation is based on detailed examination of the protein structures. In this domain-centric functional classification scheme, domains are classified into seven categories that encompass catalytic activity, cofactor-binding, responsibility for subcellular localization, protein–protein interaction, and so forth.

2 Mechanisms in the Evolution of Single Proteins and the Protein Repertoire

In the previous sections, we described the characteristics of single proteins and of the protein repertoire as it is encoded in an organism's genome. We will now focus on the processes that form the protein repertoire during evolution: firstly, whole sequences or parts thereof are duplicated and therefore the number of copies of a protein or domain is increased in a genome. This can amplify the function of the protein, but also provides material for a second mechanism: sequences, especially of duplicated proteins or domains, diverge by mutations, deletions, and insertions that produce modified structures and functions. Thirdly, whole genes or single exons recombine so that novel protein domain arrangements emerge.

2.1 Orthology and Paralogy

Before discussing the details of these three mechanisms, it is important to introduce an important notion on homology: the distinction between paralogy and orthology.

Paralogs are homologous proteins that arose via gene duplication within one organism (Fig. 7); they are also called *duplicate* genes. The redundancy created by gene duplication relaxes selection

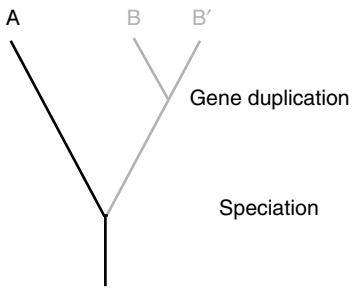

Fig. 7 Orthology and Paralogy. The tree represents the orthologous and paralogous relationships of a gene, protein, or domain. Speciation results in one copy of the gene in each species: A and B are orthologs (gray and black branch, respectively). A gene duplication event in one species (gray branch) results in B′, which is a paralog to B.

pressure and encourages the divergence of protein function. In many cases, however, paralogs still have identical or similar biochemical activities.

Orthologs are protein homologs that arose during a speciation and not a gene duplication event. Thus, orthologous proteins are still under selective pressure and will often have identical functions in different organisms. While we generally observe a core proteome of 1 : 1 orthologs across eukaryote organisms, orthologous genes can, of course, also be duplicated. If the duplication occurs *after* the speciation event, the duplicates are called *in-paralogs* or *co-orthologs*, since the orthology is ''shared'' between the duplicates. If the duplication occurs *before* the speciation event, the duplicates are called *out-paralogs*. A very useful database collects clusters of orthologous groups of proteins (COGs). Even though these groups of proteins merge paralogs and orthologs, proteins within these clusters often have similar functions.

Finally, ''horizontal'' gene transfer, as described below, introduces *xenologs* into an organism, for example, proteins that are homologous to proteins in another organism without these two organisms being directly related by descent. In addition, proteins that substitute for function in alternative pathways or in nonorthologous displacement, discussed above, could be considered *analogs*, that is, proteins of functional or structural similarity without homology.

2.2 Duplication – Mechanisms to Create ''More''

Duplication of existing building blocks drives evolution and creates paralogs as mentioned above. Haldane (1932) and Muller (1935) were the first to note the importance of duplication, later followed by more exact descriptions and estimates. The genomes of organisms of all three kingdoms of life seem to be formed by many gene duplication events, accompanied by extensive loss of genes. This is also clear at the level of domains: at least 58% of the domains in *Mycoplasma* and 98% of the domains in humans are duplicates. Nice examples of evolution by gene duplication are the HisF and HisA beta/alpha barrels, which have arisen through duplication and fusion of an ancient half-barrel.

Several different mechanisms can be responsible for duplication of existing available coding sequences. First, whole genome duplication takes place as a consequence of nondisjunction during meiosis within species or hybrids. Whole genome duplication has presumably occurred several times at least during the evolution

of eukaryotes: once in yeast, later another one in vertebrates. The model plant *Arabidopsis thaliana* shows evidence of at least two rounds.

Second, whole chromosomes or parts of chromosomes can be duplicated. There are well-known human genetic disorders, which are the result of such chromosomal duplications. Perhaps the best known of these is trisomy 21 or Down syndrome in which affected people have a third copy of chromosome 21. These types of chromosomal aberrations are called *aneuploidy*. The majority of chromosome duplications or deletions are deleterious since the duplication of a large number genes causes severe dosage imbalance in the levels of the gene products.

Third, single genes can be duplicated via tandem duplication, retroposition, or transposition as the result of ectopic recombination. Single gene duplication is assumed to be a major mechanism for the creation of recent duplicates. Tandem duplications are the result of unequal crossing-overs during meiosis. Unequal crossing-over between misaligned sequences generates a chromosome with a duplicated region and a chromosome with a deleted region.

Finally, part of a gene or one exon can be duplicated in unequal crossing-overs or replication slippage during DNA replication. Repetitive sequences can increase the chances of unequal crossing-over. Replication slippage has been found to happen for domains, resulting in long stretches of repeated domains in some proteins.

2.2.1 Horizontal Gene Transfer and Transposons

In addition to gene duplication, horizontal gene transfer (HGT) plays an important role in the evolution of prokaryote genomes. HGT is the acquisition of new genes via the movement of genetic material between species, other than by descent. Many eukaryote genes are found in bacteria, interestingly, however, not so in archaea. In eukaryotes, the rates of HGT seem much lower than in prokaryotes. The presence of many genes that arrived through horizontal transfer can seriously distort our picture of the distribution of protein and domain families and impair the reconstruction of the correct evolutionary pathway. In fact, the extensive HGT in prokaryotes led to the depiction of their phylogeny being a ''mesh'' or network, rather than a tree without a single common bacterial ancestor.

Finally, eukaryote genomes appear to be frequently shaped by jumping genes or *transposons* that move around in the genome, copying and pasting themselves. Estimates suggest that at least half of the human DNA consists of transposons, making a total of around 4 million all together. By their influence on protein structure, for example, via insertion of additional domains, they are of some influence on the shape of the protein repertoire.

2.2.2 Duplication Leads to Protein and Domain Family Expansions

While the earliest evolution of the protein repertoire must have involved the *ab initio* invention of proteins and domains, later on, this may have been replaced by the easier and more efficient reuse of existing building blocks. Thus, it is unsurprising that even the simplest bacterial genomes are the product of extensive gene duplication and recombination.

Lineage-specific expansions of protein families result from relatively recent duplications and are prominent in genomes. Across bacteria, protein, and domain families that function as transcription factors

or in signal transduction increase exponentially in number with the size of the bacterial genome. In eukaryotes, we observe the expansion of protein or domain families with very specific functions, and this can give clues on why the organisms have different physiological features. For example, the largest superfamilies in humans are mostly involved in or part of cell surface receptors, protein–protein, or cell–cell interaction, signaling, or cytoskeleton structure, and this explains why we can have so many different cell types forming intricate tissues and organs.

Proteins that function as regulators or cell-adhesion molecules are associated with the advent of multicellularity, and thus the expansion of protein or domain families that have these functions give clues as to how the multicellular organisms evolved. For example, Immunoglobulin and Cadherin domains expanded in the fruit fly as compared to the nematode worm. The functions of these domains in cell-adhesion molecules in the embryonic development of the nervous system can explain why the fly has a much more intricate nervous system than the worm.

The observed extent of domain duplication varies – across different superfamilies and across genomes. In vertebrates, such as human and mouse, each domain superfamily occurs on average in 30 different proteins, while in invertebrates, they occur in only 20 proteins. The numbers are even smaller for bacteria. Generally the duplication results in a distribution of family sizes in genomes that follow a power law, with remarkably constant parameters across organisms. This means that there are only a few highly abundant superfamilies, for example, the P-loop NTP hydrolases, NAD(P)-binding Rossmann domains and certain kinase families. This relationship was first recognized for gene family size, later for domain families or even pseudogene families, and its general implications are discussed in a later section.

2.2.3 Reconstructing the Evolutionary History of Proteins

A classic way to study evolution of a protein repertoire is to reconstruct phylogenetic trees from sequence alignments using one of several methods. One of the most reliable but also the most computationally expensive are maximum likelihood approaches, followed by parsimony, and then distance methods. From the reconstructed trees, it is possible to follow the evolutionary pathway of a protein. This permits an understanding of one protein family – more recent approaches have involved constructing trees for all or most of an organism's proteins in order to obtain an overview of the evolutionary pathway of as many components of the organism as possible. These kinds of analyses can be performed on individual domains, entire sequences, or on concatenated alignments of multiple proteins or domains. Unfortunately, xenologs, that is, homologs in organisms that are not directly related, create difficulties. Therefore, it is advisable to consult several phylogenetic trees since their consensus may reflect the organisms' true evolutionary relationships best.

By reconciling a tree with a species tree, it is then possible to estimate where the duplication and speciation events took place and this differentiates orthologs from paralogs (Fig. 7). This method is vital in phylogenomic-type approaches, which attempt to elucidate function from a proteins phylogenetic location within a tree with respect to homologous proteins of known function.

2.3 Divergence after Duplication

In the absence of duplication, any mutation that occurs is under selective pressure to maintain the protein's structure and function. Once a domain or protein has duplicated, this pressure is relaxed and one copy of the domain can evolve a new or modified function. This can occur by sequence divergence or by combining with other domains to form a multidomain protein with a new series of domains. The positive, negative, or neutral effect on the function determines if the duplicate is retained. Apart from changes in sequence, structure, and function, which we discuss below, duplication also relaxes selection pressure on other characteristics, for example, gene regulation or expression patterns.

Many eukaryotes are diploid, which means they have two copies of each chromosome. Thus, there naturally exists a duplicate of each gene. The diploid nature of many organisms delivers potential for divergence and modification of protein function even without any additional gene duplication. This is exemplified in many well-known cases of dominant and recessive mutations that are carried through populations. One example is the recessive mutation that is the cause of sickle cell anemia, which we discussed earlier.

2.3.1 Changes in Sequence

The first level of changes that occur are at the nucleotide level. Mutations can affect a single nucleotide (point mutations) or several adjacent nucleotides (segmental mutations). Depending on the type of change caused by the mutational event, there can be substitutions, recombinations, deletions, insertions, or inversions. Substitution mutations can be transitions, where one purine is replaced by a different purine or transversions, where a purine is replaced by a pyrimidine or *vice versa*. If these changes happen in protein-coding regions, they can affect the amino acid sequence in two different ways:

Many single nucleotide changes are called *synonymous* substitutions, as they do not alter the resulting amino acid due to the redundancy of the genetic code. Synonymous substitutions are not as much affected by selection, as the protein sequence and structure remains the same, and they display similar rates across different protein families. They can therefore serve as a measure of the overall substitution rate and the absolute evolutionary distance between two sequences.

In contrast, *nonsynonymous substitutions* change the resulting amino acid and are likely to affect the protein and fall under selection. As a consequence of different selection pressures on different protein families, the nonsynonymous substitution rates vary enormously amongst protein families.

We usually distinguish three different effects of sequence changes: deleterious (or negative), neutral, and advantageous (or positive) mutations. The neutral effect of, mostly, synonymous substitutions has a long history in research. One common way to analyze for advantageous mutations is to compare the frequency of nonsynonymous and synonymous substitutions. Examples of advantageous mutations seem relatively rare, and are observed in resistance or pathogen defense genes, for example, in MHC proteins. It is very difficult to estimate the absolute or relative mutation rates, as many different factors affect them: the level of expression of the gene, the function of the resulting protein, the

essentiality of the gene, or the relative amino acid cost.

2.3.2 Changes in Function

Once a gene is duplicated within a genome, one of the two copies is free to evolve, while the first can maintain the original function. This evolution may produce modified or new molecular functions that act within the same biological process, or it could create functionality within an unrelated biological process. We distinguish three major effects on protein function after a duplication event. First, the redundant sequence can have a highly negative effect on the fitness of the organism and is consequently silenced. The whole gene is lost or turned into a ''dead,'' untranscribed *pseudogene*. This is a very common process. Second, the redundant protein can evolve a new function that is different from the original function, for example, by sequence divergence or combination with a novel domain partner, and this process is called *neo-functionalization*. Last, if the original gene has multiple functions, they may become split between the two copies, a process called *subfunctionalization*. In eukaryotes, neofunctionalization is much more common than subfunctionalization.

The evolution of domain function is even more complicated, since a domain can either have an independent function, and/or contribute to the function of a multidomain protein in cooperation with other domains. In order to assess domain function evolution, knowledge of the three-dimensional structure is vital. Todd et al. found that for most domains within a superfamily the reaction chemistry is fully or at least largely conserved. The substrate specificity, rather than reaction chemistry, is modulated; this often occurs via changes in the kind of domains adjacent to the catalytic domains, embellishments in the active site, or by variations in the oligomeric state of relatives. Catalytic residues can ''migrate'' with respect to their position in the amino acid sequence, but their relative position in the three-dimensional structure is mostly preserved. In sum, domain function evolution occurs in two major ways: first, a domain can perform the same function, but in different protein contexts, that is, with different partner domains. Second, a domain may diverge and acquire a novel or modified function.

The way in which an individual protein or protein domain will evolve is very much dependent on the interactions it maintains with other molecules. There is a high level of evolutionary constraint on enzyme binding sites that have chemically specific ligands and restricted binding orientation so that mechanistically the function can still be maintained. Similarly, regulator proteins that bind to specific DNA or RNA sequences also need to maintain a very specific binding site. Conversely, a protein that binds a receptor protein is freer to evolve as the receptor may co-evolve at the same time. Therefore, proteins involved in such interactions can evolve more quickly than proteins that must bind and localize a specific small molecule.

This is exemplified by the fast-evolving four-helical cytokines, specifically human and mouse Interleukin-5, the sequences of which are 70% identical, but they will no longer cross-bind to one another's receptors. Such fast-evolving proteins often seem to have functions with the immune system – a facet of living organisms, which needs to evolve quickly in order to adapt to the many new and changing invasive viruses and bacteria present. For immunoglobulins, crucial for antigen recognition in higher eukaryotes, the ability to evolve quickly is indispensable.

Indeed, they have evolved the ability to switch only one of their domains (the variable domain or V-set) by alternative splicing in order to create more combinations, thus increasing the likelihood of antigen recognition.

In sum, the nature of a protein domain's specific interactions, and the number of interactions it is physically a part of, is likely to impact greatly the rate of evolution for that particular protein or at least the domains within it. The greater the number of interactions and the more constrained structurally the binding partners, the slower the evolution.

2.3.3 Structural Tolerance to Amino Acid Changes – a Case Study on Globins

Implicitly, alterations within the amino acid sequence of a protein will produce changes in the resulting structure. However, the effect on the structure is dependent on where in the protein the change occurs. Traditionally, there have been two approaches to understand tolerance to amino acid changes – theoretical comparison of related sequences and structures from present-day organisms and mutagenesis experiments. In mutagenesis experiments, the roles of specific residues in the folding and stability of a protein are probed by replacing them with alternative residues.

These two approaches convey a similar message on acceptability of mutations in proteins. The hydrophilic exterior of a protein is tolerant to a wide variety of mutations. However, there is a restriction on the choice of mutations in the protein interior; in general, mutations conserve the hydrophobic nature of the core. Thus, the nature and accessibility of the side chains play an important role in the folding and stability of proteins.

Globins represent wonderful examples of how evolutionarily related proteins can be of similar three-dimensional structure and function, but of hardly recognizable sequence similarity. The first two protein structures to be determined, that of sperm whale myoglobin and horse hemoglobin, have only 28% sequence identity. Lesk and Chothia examined the relationship between sequence, structure, and packing in globins in order to understand the effect of sequence divergence on structure and to understand how proteins adapt to mutations.

Although there are approximately 150 residues in globins, the principal determinants of the three-dimensional structure are the 59 residues that are involved in the packing of helices and in the interactions between the helices and the haem group. Only half of these residues are buried. Any mutations of the buried residues retain nonpolar sidechains, although the amino acid shape and size vary. The interface structure between the alpha helices within the globin domains is extensively conserved, except for some shifts and rotations between pairs of helices as a consequence of dense helix packing. If a mutation at the interface changes the volume of the amino acid side chain, the helices move to adjust the packing.

Rare or disallowed changes in globins illustrate the global effect of mutations on the structure and how they are accommodated. If the interface residues switched instead to a completely new set of contacts, the stability of the contact would be lost as the complementarity of the helix surface is compromised beyond allowed limits of variability. For example, a single insertion in the helix interior would turn at least part of the interface by 100°, destroying surface complementarity. Thus, insertions and

deletions are never found within a globin helix. Furthermore, mutations in the individual residues in contact with the haem are difficult to accommodate as the haem has comparatively little flexibility. In order to maintain the geometry of haem packing, changes in helix packings are coupled and do not occur independently.

2.3.4 Changes in Structure

How far can sequences diverge given the requirements of structural stability? In order to understand the relationship between divergence of sequence and structure, Chothia and Lesk compared 25 structures from eight different protein families. They determined the common core of a protein family by individually superposing the main-chain atoms of major secondary structure. The core regions undergo structural change as their sequences diverge and accumulate mutations. The further the sequences diverge and the lower the sequence identify, the small is the core common to the proteins. For those pairs of proteins, whose sequence identity is 50% or more, 90% of the residues of the individual structures are part of their common core. In contrast, for pairs whose residue identity drops to about 20%, their common cores contain commonly half of the residues in the individual structures. The structural differences in the common cores of members of individual protein families consist mainly of changes in the relative position and orientation of packed secondary structures and local changes in case of beta-sheets. A more recent study of the four-helical cytokines found around 5% of sites within the proteins that had any kind of minimal hydrophobicity or volume conservation within the hydrophobic cores of the proteins.

This demonstrates how rapid evolution can take place at the sequence level while still producing the same or a similar protein structure. There is, however, also great scope for alterations to protein structure.

First, secondary structure can be changed and additional regions of secondary structure (decorations) can be added around the core. Frequently, N- and C-terminal extensions are added to structural domains. Occasionally, we observe wonderful snapshots of such structural evolution in progress. For example, recent work by Newlove shows how one part of a protein domain in closely related Cro proteins can switch its secondary structure depending on its oligomeric state (Fig. 8). Other fold changes include divergent relationships between proteins with distinct topological isomers such as the catalytic domain of carboxypeptidase G_2

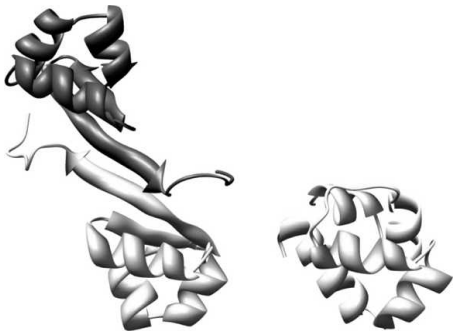

Fig. 8 Cro protein evolution. The dimeric Cro lambda repressor protein is shown on the left-hand side (PDB ID: 1cop with the different domains shaded differently) and on the right is the evolutionarily related Cro 434 protein (PDB ID: 2cro). Secondary structure switching occurs at the dimer interface of Cro lambda, which forms beta-strands, compared to the C-terminal helices in the equivalent position in Cro 434.

and the aminopeptidase from *Aeromonas proteolytica*, and interchangeable parts, that is, topological differences, but similar secondary structures, for example, triabin and the lipocalins.

Second, oligomeric state also contributes to the evolution of the protein repertoire. Paralogs of proteins can have different oligomeric dependencies for stability and functionality. Alteration of oligomeric state can be a mechanism for enormous functional, as well as structural, divergence as seen in the cupin family. Often, within multimeric protein structures we observe*domain-swapping*, that is, individual monomers become intertwined and even more dependent on one another. Indeed domain-swapping has been suggested as a mechanism of protein evolution toward multimerization. Thus, in multimeric proteins, we see again how the modularity of proteins, that is, by combining different numbers of domains, provides a fantastic resource for a variety of evolutionary processes.

Overall, the variety of evolutionary mechanisms, such as insertion, deletion and substitution of sequences, circular permutations, strand invasions and withdrawals, hairpin flips and swaps, can eventually lead to changes in the protein fold, and Grishin et al. detail many wonderful examples. Circular permutations are alterations of protein connectivity evident through ligation of the termini and cleavage at another site. Strand invasion refers to the insertion of a strand into a beta-sheet such that hydrogen bonds have to be broken in the existing sheet, and reformed with the inserted strand. Strand withdrawal means the removal of a strand. In hairpin flips and swaps, beta-strands are internally flipped, more commonly, this is observed for strands adjacent to one another – this creates or removes crossing loops.

This illustrates how the evolutionary relationship between two proteins, that is, homology, and similarity between their structures are different features and how one does not necessarily determine the other. Rapid evolution can take place at the sequence level and still produce a similar structure and *vice versa*.

2.4 Recombination – Mechanisms to Create "Novel Combinations"

Another way for Nature to diversify the repertoire of proteins is to shuffle their units, the domains, around and create novel combinations. Already 30 years ago, examination of protein structures showed that many proteins are formed of two or more domains; and domains from the same or from different superfamilies combine with each other. Several molecular mechanisms underlie this reshuffling. The major molecular mechanism that leads to multidomain proteins and novel combinations is nonhomologous recombination of domains, sometimes referred to as *domain shuffling*.

There is evidence that in eukaryotes there is a tendency for exon boundaries to coincide with domain boundaries, which suggests that the proteins are formed by intronic recombination.

There is a lot of debate as to whether introns were inserted early on in evolution or late. A detailed study on the conservation of the introns and exons between proteins of known structure revealed that probably some introns were inserted earlier and others later – and, in some cases, their positioning was more conserved within superfamilies than

in others. Most of the intron positions showed little or no conservation supporting the view that intron insertion appeared only after the duplication or speciation. In contrast, some extreme examples, for example, the four-helical cytokines, showed an amazing conservation of intron positions with respect to secondary structure elements, and this implied that they were inserted already in the proteins' common ancestor.

Another important recombinatorial mechanism, especially in eukaryotes, is the fusion of genes leading to so-called *Rosetta-Stone sequences*. Gene fusion seems more common than splitting or fission of genes.

2.4.1 Most Proteins Have More than One Domain

Proteins form complex networks of interactions. Thus, even a modest increase in the number of domains in a protein could result in numerous new interactions. Small proteins generally contain just one domain. Large proteins are more often formed by combinations of domains. The total number of domains found in one protein and their relative orientation determines what we call the protein's *domain architecture*. The majority, or at least two-thirds, of proteins consist of two or more domains in prokaryotes and an even larger fraction in eukaryotes. Higher eukaryote proteins also have, on average, more different types of domains than lower organisms. Last, eukaryote proteins acquire domains additional to those seen in their prokaryote orthologs, and this tendency has been termed *domain accretion*. The increasing complexity of domain architectures in higher eukaryotes (Fig. 6) has been correlated with their increased physiological complexity, since more domains in a protein allow a greater variety of interactions and functions.

2.4.2 The Repertoire of Domain Combinations is Limited and Highly Biased

Even though most proteins consist of several domains, the repertoire of combinations of different domains seems very limited. The proteins from more than one hundred different organisms contain only several thousand different combinations of two-domain superfamilies. This is far fewer than would be possible given the total number of about 1200 known superfamilies or the number of multidomain proteins per proteome. This fraction is likely to decrease even more if membrane proteins are included.

There are a few domain superfamilies that are highly versatile and have neighboring domains from many superfamilies, while most superfamilies have only a few different types of adjacent domains. The distribution of the number of partner superfamilies per superfamily follows a power law, like the distribution of superfamily sizes mentioned above. A most versatile superfamily is, for example, the P-loop hydrolase with more than 80 different combination partners in the human genome. We also observe that particular combinations of domains occur in many different proteins, such as the combination of SH3 and SH2 domains is part of many signal transduction proteins. These recurring domain combinations are *supra-domains*, for example, combinations that are duplicated as one unit and reused in different proteins. Thus, supra-domains represent evolutionary units larger than single domains – and they appear to be a major part of the protein repertoire.

2.4.3 The Sequential Order of Domains and Their Geometry are Conserved

Since most proteins consist of multiple domains, and domains determine the

function and evolutionary relationships of proteins, it is important to understand the principles of both domain combinations and interactions. If the same domain combination is observed in two different proteins, one possibility is that they have assembled independently by different recombinatorial routes. We assume, however, that most instances of the same two-domain combination or domain architecture have evolved from the same ancestor, and there are several lines of evidence that support this.

First, three-dimensional structural analyses of individual protein families such as the Rossmann domains have shown that proteins with the same domain architecture are related by descent, that is, evolved from one common ancestor. This may even be true for most two-domain protein families of known structures in the current databases. Second, with only a small fraction of exceptions, two domains occur in only one N- to C-terminal order in structural assignments to genome sequences. This conservation of domain order is likely to be historical instead of functional, as a very similar interface and functional sites could be formed by two domains in either order, for instance, given a long linker. Finally, proteins sharing a series of domains also tend to have the same function, which is rarely the case if domain order is switched.

In addition to their conserved sequential order in a protein, the spatial arrangement, or domain *geometry*, is remarkably conserved if the two domains are homologous. This has first been shown for the example of Rossmann domains and their catalytic partner domains, but is possibly true for most of the domain combinations found in SCOP. Studies of small numbers of families of protein complexes, where the interdomain geometry occurs across different polypeptide chains, have also revealed extensive conservation of geometry; and there is a tendency for geometry of interaction of protein domains to be the more conserved, the more similar the domain sequences are.

These results suggested that for proteins of unknown structure, the quarternary structure and protein complex geometry can usually be modeled on the basis of homologous polypeptide(s) of known structure; and impressive examples of such protein models of complexes are the yeast ribosome and exosome.

2.5 Selective and Random Processes

As illustrated above, the sequence, structure and function of proteins are tightly linked and place strong constraints on evolution. In contrast, many evolutionary changes seem to occur in a random fashion. Selection then modifies the outcome of these processes: it favors advantageous changes, rejects disadvantageous changes, and tolerates changes of neutral effect. Some changes may be of neutral effect. This is also true at the level of proteins and domains.

On the one hand, we have seen that many domain or protein families have properties useful in a wide range of contexts; it seems obvious that certain specialized biochemical functions are selected more often than others. Examples are the C2H2 and C2HC zinc-finger domains, which are found in a wide variety of proteins associated with DNA-binding, such as transcription factors. From a structural point of view, there is a tight interplay between the folding kinetics, the stability, and the function of a protein, and the so-called *designability* of a protein, domain, or domain combination could also be an

important selection criterion. According to this view, certain folds have topological properties that make them especially *designable* that is stable, modular, and functional. One example is the TIM-barrel fold with a uniquely symmetrical construction.

On the other hand, one of the most striking observations in recent years was that mathematical laws seem to govern many biologically relationships, and it is difficult to imagine how specific selective procedures may have produced them. In particular, power laws describe the distribution of gene family sizes pseudogene families, the lengths of proteins in terms of domains, or the domain superfamilies among folds. Power laws also describe properties of scale-free networks that depict the relationships or interactions between proteins in metabolic pathways and domains within proteins.

Stochastic birth, death, and innovation models (BDIM) deliver one explanation of the power laws. They describe a *preferential attachment* mechanism in which the ''fit get fitter'' : large protein families tend to get larger; highly versatile domains tend to get even more different combination partners. Innovation comprises both the divergence of sequences and processes that introduce novel sequences into a genome, such as horizontal gene transfer. BDIMs approximate the observed power law distributions remarkably well and support a random mode in evolution. However, they basically ignore the individual properties of proteins and domains – a most crucial abstraction and simplification.

3 Summary and Conclusions – Evolutionary Principles

If life was like a book, written in an unknown language, then the words of this language may be the proteins. These proteins form sentences of pathways. Several sentences in a paragraph might correspond to an organelle; organelles are parts of cells, and cells of organisms. Here, we considered the protein vocabulary, and how the protein words are made of syllables called *domains*. Since the first determination of protein structures some 40 years ago, researchers have been studying these basic units, the domains. Now that the complete genome sequence of many organisms and their domain assignments are available, we can start to understand the rules of how domains form proteins and how our molecular vocabulary evolved.

We have given a description of the repertoire of proteins and their domains, how it has evolved thus far, and the mechanisms involved in bringing about this evolution. Our description revolved around the relationship between sequence, structure, and function of these domains, and how these characteristics determine the rate of protein evolution. We showed how the duplication, recombination, and divergence of protein domains had an enormous impact on the protein repertoire as we see it today.

In a very succinct review, Chothia and colleagues gave two possible reasons why these mechanisms of domain duplication, divergence, and recombination take place so commonly rather than via *ab initio* protein construction. The first sets of proteins created must have arisen via *ab initio* invention. Once an initial set of domains and proteins had evolved that was varied enough to support a basic form of life, it was much faster and more efficient to use duplication and recombination to create new protein combinations with altered functions. In addition, once repair mechanisms present in DNA replication

and protein synthesis had been created, they made the *ab initio* process for domain invention too costly and difficult to be used very often.

In addition, many other processes, such as regulation of gene expression, alternative splicing, RNA editing or protein modification, determine how many and which kinds of proteins are active in a particular cell at a particular point in time. They represent mechanisms by which the complexity of the protein repertoire that is active in a cell is increased and delivers one explanation of why higher eukaryotes can do with relatively few genes. They are important mechanisms that deserve separate, more detailed description, and go beyond the scope of this discussion.

For an even more complete understanding of evolution, an integration of most different fields will be necessary: ''genomics'' analyses will have to join molecular evolution approaches; structural biologists, population geneticists, and experimentalists will have to interact more closely. Today, we already see some fruitful outcomes of such integrative approaches. One example is the recent work by Lynch and Conery. The authors analyze the relationship between the genome complexity and population size: species of large populations, such as bacteria, have small genomes, while for species of small populations, such as humans, we observe the opposite. Another beautiful example examines the link between molecular sequence variation and molecular and macroscopic phenotype; and this is for the chaperone Hsp90, which acts as a buffer and regulator in response to environmental changes. The chaperone assists the maturation, that is, the correct folding, of many key regulatory proteins. Thus, genetic variation can accumulate in genomes and can remain phenotypically silent due to the buffering by the chaperone. Upon environmental changes, however, for example, under stress, the chaperone's function is challenged and it releases novel phenotypes of folded protein structures.

While the groundwork for an understanding of protein structures and their evolution has been done, the exact interaction between selection and random processes is not yet clear. Only future comprehensive, integrative analyses of domain superfamilies and their combinations will reveal how the selection, in combination with random processes, can have produced a most complex protein universe. Thus, eventually, once we fully understand the vocabulary of proteins and grammar of protein evolution, we will be able to read the whole story of the book of life.

Keywords

Extein
The exteins are the flanking polypeptides interrupted by an intein.

HINT Domain
The HINT domain is the common structural folding pattern shared by **h**edgehog proteins and **int**eins.

Homing Endonuclease
Homing endonucleases recognize and cleave a target allele, facilitating the lateral transfer of the gene encoding an intein (or intron) to a homologous allele lacking the intervening sequence.

Intein
Inteins are intervening protein sequences that facilitate their own posttranslational excision from, as well as the ligation of, the flanking polypeptides.

Protein Splicing
Protein splicing is a posttranslational autoprocessing event by which an intervening protein facilitates its own excision from flanking polypeptides and the specific ligation of those polypeptides.

Trans-splicing
Protein splicing facilitated by a split intein. Intein reassociation must precede protein splicing in trans.

Protein splicing is a posttranslational autoprocessing event by which an intervening polypeptide sequence, the intein, facilitates both its own excision from flanking polypeptides, or exteins, as well as the ligation of the exteins. Since the discovery of protein splicing in 1990, significant progress has been made in elucidating the

chemical mechanism of protein splicing by both biochemical and structural studies. The more recent discoveries of inteins that can facilitate protein trans-splicing, inteins that splice via noncanonical mechanisms, and bacterial intein-like domains have provided further insight into the mechanism and evolution of protein splicing. The study of protein splicing has also deepened our understanding of related forms of protein autoprocessing, particularly the processing of hedgehog proteins. Inteins have also found wide use in biotechnology applications, including systems for protein purification, ligation, and cyclization.

1 Discovery of Protein Splicing

Protein splicing was discovered in 1990 in *Saccharomyces cerevisiae* (*Sce*). The *Sce VMA1* gene is interrupted by an intervening sequence, which is absent from homologous genes in related organisms. The split gene is transcribed into the corresponding full-length mRNA, with no spliced mRNA product detected. Equal amounts of ATPase and intein are detected using Western blot, indicating that the intervening gene is translated. Protein-splicing elements were also discovered in the *recA* gene of *Mycobacterium tuberculosis (Mtu)* and the DNA polymerase gene in *Thermococcus litoralis*.

The experiments that followed defined the essential elements for a functional intein. The fact that splicing occurs if the intein is inserted into a foreign context indicates that the intein itself contains all of the genetic information necessary for protein splicing. Inteins have homology to homing endonuclease domains similar to those found in mobile introns, although it was demonstrated by deletion analysis that the endonuclease activity is not essential for protein splicing. Essential residues were identified by analysis of the modulation of protein splicing by mutation. The nucleophilic cysteine or serine flanking the intein, as well as the conserved asparagine at the C-terminus of the intein, play a role in efficient *in vivo* protein splicing.

2 Chemical Mechanism of Protein Splicing

2.1 N-S (or N-O) Acyl Rearrangement

The first step of protein splicing involves the formation of a linear thioester or ester intermediate at the N-terminal splice junction. (See Fig. 1.) This ester intermediate is the result of an N-S or N-O acyl shift of the peptide bond involving the amino group of the N-terminal cysteine or serine. A linear thioester intermediate was first observed in a *Pyrococcus* sp. GBD Pol intein in which the N-terminal serine was replaced by cysteine. The thioester was detected by reaction with neutral hydroxylamine or ethylenediamine, which results in cleavage at the N-terminal splice junction. The splice junction was identified by analysis of the C-terminal hydroxamate residue of the N-terminal extein after hydroxylamine-induced cleavage. A thioester intermediate was also observed in the *Sce* VMA intein, which naturally contains an N-terminal cysteine.

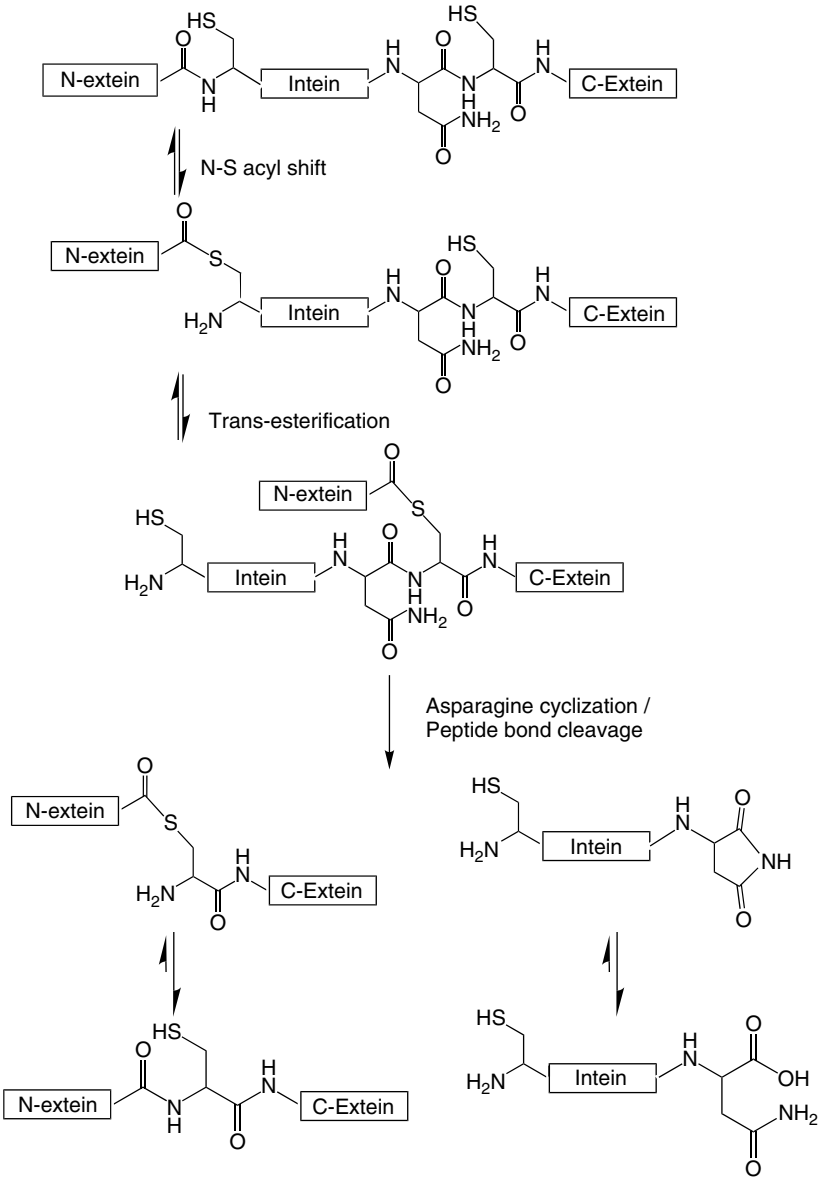

Fig. 1 Chemical mechanism of protein splicing. The nucleophilic residues are shown as cysteine in this example, although the upstream can be cysteine or serine and the downstream nucleophile can be cysteine, serine, or threonine.

Not all inteins initiate protein splicing by an N-S or N-O acyl shift of the scissile peptide bond, as inteins lacking an N-terminal nucleophile have been identified, three of which have been shown to splice. This suggests that these inteins have evolved to splice by bypassing the initial N-S or N-O shift through a direct attack by the

downstream nucleophile on the upstream scissile peptide bond. In the *Methanococcus jannaschii* KlbA intein, replacement of the N-terminal alanine with cysteine or serine yields significant amounts of spliced product, and a double mutant of the intein N-terminal alanine to cysteine and the N-terminal cysteine of the C-exteins (The term C-extein will refer to the C-terminal extein segment, and N-extein will refer to the N-terminal extein segment. Amino acid numbering begins with the first residue of the intein, such that the ''N-1 residue'' is the C-terminal residue of the N-extein and the ''C+1'' residue is the N-terminal residue of the C-extein.) to alanine can promote N-terminal cleavage by neutral hydroxylamine. The fact that this modified intein is able to facilitate an N-S acyl shift suggests that the replacement of the N-terminal nucleophilic amino acid of the intein by alanine may have occurred recently.

Uncatalyzed N-O or N-S acyl shifts have not been detected, but are known to occur in peptide bonds involving the α-nitrogen of serine or threonine in the presence of strong acid. It has been suggested that catalytic strain may serve in both accelerating the rate of this step of protein splicing as well as in shifting the equilibrium more favorably toward the ester. For instance, in the crystal structure of the *Mycobacterium xenopi* (*Mxe*) GyrA intein, the scissile bond is in a cis conformation. In addition, distortion of the scissile bond in a catalytically active *Mxe* GyrA intein is suggested by NMR data obtained using a segmental isotopically labeled intein. These data include an abnormally low one-bond dipolar coupling constant for the scissile bond and an unusually large upfield proton shift for the amide proton. Experimental evidence suggests that this bond strain is mechanistically relevant, as the identity of the N-1 residue of the *Mxe* GyrA intein has an effect on both splicing yield *in vivo* and DTT-induced N-terminal cleavage *in vitro*. In the crystal structure of the *Sce* VMA intein, the backbone τ angle of the N-1 residue is distorted by 10°. For this intein as well, a subset of mutations of the N-1 residue prevents protein splicing and DTT-induced N-terminal cleavage, and another set of mutations shifts the equilibrium of the N-S acyl shift to favor the thioester On the other hand, no distortion of the scissile bond is observed in crystal structures of nonsplicing mutants of the *Sce* VMA intein or the *Synechocystis* sp. PCC6803 (*Ssp*) DnaB intein.

2.2 Transesterification

The second step of protein splicing involves the transesterification of the linear ester by the downstream nucleophile (See Fig. 1). The result is a branched ester intermediate, first discovered in the *Psp*-GBD Pol intein. The branched intermediate was identified by reduced mobility in SDS-PAGE and by the results of sequential Edman degradation, in which two amino acids were released at each sequencing cycle, consistent with the N-terminal sequences of the N-extein and intein. Raising the pH shifts the equilibrium to the amide, and the lowering of the pH restores the branched ester, indicating full reversibility. An ester bond between the side chain of the downstream serine and the N-extein was discovered by trapping the branched ester by denaturation and cleaving it under mildly alkaline conditions. Branched thioester intermediates are also observed with inteins with cysteine at the C+1 position.

The upstream and downstream nucleophilic side chains are less than 4 Å apart in a crystal structure of a *Sce* VMA intein, suggesting facile transesterification. However, in the crystal structures of the *Sce* VMA and *Ssp* DnaB inteins, the nucleophilic side chains are separated by 8.5 and 9 Å, which suggests that either these inteins are not in an active form or require a significant conformational change to allow splicing. The downstream cysteine residue in the *Mtu* RecA intein has an unusually low pKa of 5.8, which may indicate that the transesterification can be facilitated by the unique dielectric environment of the intein. On the other hand, general base catalysis may facilitate transesterification in the *Sce* VMA intein, as the amino group of the intein N-terminal cysteine produced by the N-S shift may improve the nucleophilicity of the N-terminal thiol of the C-extein.

2.3 Asparagine Cyclization Coupled to Peptide Bond Cleavage

The third step of protein splicing is the cyclization of the C-terminal asparagine of the intein, which is coupled to cleavage of the peptide bond joining the intein and C-extein. (See Fig. 1.) Spontaneous asparagine cyclization in proteins typically results in side-chain deamidation and involves nucleophilic attack of the main-chain amide nitrogen on the side-chain carbonyl carbon to form an amidosuccinimide, followed by hydrolysis to either aspartic acid or iso-aspartic acid. An alternative mode of cyclization involves attack of the side-chain amide nitrogen on the main-chain carbonyl and leads to aminosuccinimide formation coupled to peptide bond cleavage. This may be preceded by deprotonation of the side-chain amide nitrogen, as indicated by studies of model peptides in which the rate of cleavage increases with pH. Spontaneous peptide bond cleavage via succinimide intermediates is observed in some long-lived proteins, such as α-crystallin.

The third step of protein splicing was elucidated by the isolation and analysis of C-terminal aminosuccinimide residues formed during protein splicing mediated by the *Psp*-GBD Pol intein and the *Sce* VMA intein. Branched intermediate can accumulate if the conserved asparagine at the C-terminus of the *Psp*-GBD Pol intein is mutated to aspartic acid or glutamine.

It has been proposed that the conserved penultimate histidine residue plays a role in asparagine cyclization. For instance, protein splicing is arrested and branched intermediate accumulates if the penultimate histidine in the *Psp*-GBD Pol intein is mutated to alanine. Protein splicing can be enhanced in inteins lacking a penultimate histidine by introducing a histidine residue by mutation. Structural evidence points to a role for the penultimate histidine as well. For instance, in the *Mxe* GyrA crystal structure, His197 is in a position to serve as a proton donor to the backbone amide nitrogen of the scissile bond. In the *Ssp* DnaB structure, the penultimate histidine could make a hydrogen bond with the main-chain carbonyl oxygen of the adjacent asparagine. However, at least 27 inteins lacking a penultimate histidine are known. Some of these inteins splice in the absence of the histidine residues, and in some cases splicing is impaired if the penultimate residue is replaced with histidine by mutation. It is possible that this histidine may play a role in coordinating the steps of protein splicing rather

than facilitating the asparagine cyclization directly.

Two inteins with C-terminal glutamine can facilitate splicing, as can an intein with a C-terminal aspartic acid. Although it seems likely that these inteins splice via cyclization of the C-terminal residue to a glutarimide or succinanhydride, respectively, excised inteins with cyclized C-terminal residues have not been detected, even if the C-terminal glutamine is changed to asparagine. This is surprising because other inteins with C-terminal aminosuccinimide residues have been isolated, and suggest that the noncanonical inteins may splice via an alternative mechanism.

2.4 Finishing Reactions

Asparagine cyclization leads to the excision of the intein and leaves the exteins linked by an ester. The completion of protein splicing thus requires the hydrolysis of the C-terminal aminosuccinimide residue of the intein and the conversion of the thioester or ester bond ligating the extein segments to a native peptide bond (See Fig. 1). The N-O or N-S acyl rearrangement is probably uncatalyzed because the rearrangement in synthetic depsipeptides occurs in less than a minute, much faster than the measured rates of *in vitro* splicing reactions. However, a crystal structure of a spliced *Sce* VMA intein shows that the N-terminal amino group of the intein could stabilize the oxythiazolidine intermediate in the S-N rearrangement. Enhancement of the rate of this rearrangement could prevent hydrolysis of the nascent ester-linked extein segments. The hydrolysis of the C-terminal aminosuccinimide is probably uncatalyzed as well, as the timescale of the isolation of inteins containing C-terminal aminosuccinimide is consistent with the 2.3-h half-life of the L-imide in model peptides.

3 Intein Structures

3.1 Domain Organization

Inteins can vary in size from 134 to 608 residues, and many are themselves interrupted by a homing endonuclease domain. In general, inteins contain six conserved motifs related to protein splicing, which are labeled in Fig. 2 according to the revised nomenclature of Pietrokovski. Conserved elements include an N-terminal nucleophilic residue (either Cys or Ser) in block N1, a conserved aspartic acid or glutamic acid in blocks N2 and N4, a TXXH motif in block N3, and a His-Asn sequence in block C1. Inteins are flanked at the C-terminus with a conserved cysteine, serine, or threonine residue. Although inteins can promote protein splicing in a foreign context, the efficiency of protein splicing can

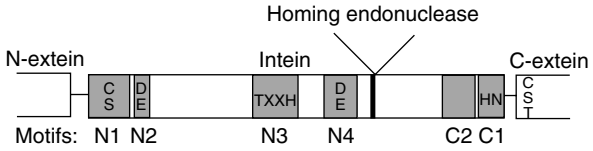

Fig. 2 Conserved elements in a typical intein. The motif nomenclature is that of Pietrokovski. Highly conserved residues are indicated in bold.

be influenced by the extein amino acid sequence. Random mutagenesis and genetic deletion studies have shown that the homing endonuclease domain is not required for protein-splicing function, and about 10% of inteins lack this central endonuclease domain, yet such mini-inteins can still promote splicing. This discovery led to the development of inteins split within the endonuclease domain that could splice in trans both *in vivo* and *in vitro*, and the discovery of a naturally split intein in *Synechocystis* sp. PCC6803.

3.2 Three-dimensional Structures

The crystal structure of the VMA intein from *S. cerevisiae* consists of two separate domains: the protein-splicing domain, which contains both termini of the protein, and the endonuclease domain. The protein-splicing domain is an elongated structure of seven β-sheets in two substructures. A crystal structure of a zinc-inactivated *Sce* VMA intein with the endonuclease domain deleted shows that the N-terminal scissile bond is in a strained trans conformation, although a later crystal structure with short N- and C-terminal exteins has a normal transpeptide bond at both splice junctions. The *M. xenopi* GyrA intein forms a flattened ''horseshoe'' shape, the edges of which are composed of two long, curved antiparallel β-stands. Two three-stranded β-sheets, related by pseudo twofold symmetry, form a cleft in which the N- and C-terminal residues are separated by less than 3 Å. The N-terminal scissile bond is in a cis conformation. The crystal structure of the *Ssp* DnaB mini-intein has a similar overall folding pattern, but exhibits strain in the C-terminal scissile bond and two separate catalytic sites that may be separately responsible for the reactions at the intein N- and C-termini. The crystal structure of the Hedgehog autoprocessing domain reveals that Hedgehog domains and inteins share a common fold, as is expected from their sequence homology. This common fold is called the *HINT module* (for Hedgehog-INTein).

4 Protein Splicing in Trans

The discovery of minimal inteins provided the impetus for the search for further intein modifications that would allow protein splicing in trans (See Fig. 3). Trans-splicing was first demonstrated *in vivo* in *Escherichia coli* using a plasmid encoding the *Mtu* RecA intein in which the DNA encoding the central homing endonuclease domain was replaced by a linker containing overlapping translation stop and start codons. Protein trans-splicing *in vitro* was demonstrated using separately expressed fragments, one consisting of *E. coli* maltose-binding protein fused to the 105 N-terminal residues of the RecA intein and the other consisting of the 107 C-terminal residues of the intein fused to a domain containing a His-tag. These fragments could be reassociated by denaturation followed by joint renaturation and efficiently mediated *in vitro* protein splicing. This trans-splicing system was improved by the generation of a semisynthetic split intein by replacement of the C-terminal expressed segment of the trans-splicing intein with a synthetic polypeptide. A similar trans-splicing system was derived from the *Psp*-GBD Pol intein, although the homing endonuclease domain could not be deleted without loss of function.

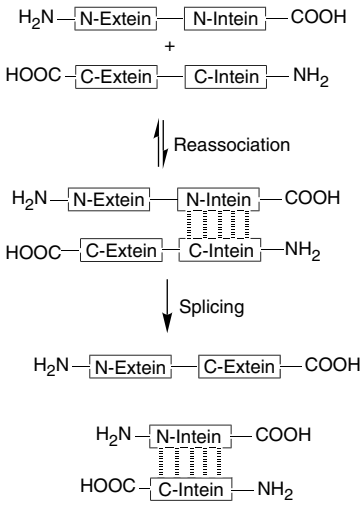

Fig. 3 Protein splicing in trans. The vertical lines are used to suggest interactions between the N- and C-intein segments.

A naturally split intein was discovered to interrupt the DnaE protein in *Synechocystis* species PCC6803. The N-terminal segment of the DnaE protein is fused to the N-intein, and the C-intein is fused to the C-terminal segment of the DnaE protein. The genes encoding these two proteins are separated by 745 kb of DNA and reside on opposite strands. The split intein can splice *in vivo* if overexpressed in *E. coli*. As a result of this discovery, an *in vitro* trans-splicing system using the DnaE intein was developed that could mediate splicing without the need for joint denaturation and renaturation, which has been used to discover zinc as an inhibitor for protein splicing, allowed for extensive kinetic analysis of protein splicing, and encouraged the development of biotechnological applications and protein-splicing screening systems that will be described below.

5 Kinetic Studies of Protein Splicing

Because inteins facilitate an autoprocessing reaction, they serve as both enzyme and substrate and are not true "catalysts." To study the kinetics of the protein-splicing reaction, one must be able to activate an intein from an inactive precursor. This was first accomplished in detail with the split *Ssp* DnaE intein. The rate constant of trans-splicing at 23 °C was 6.6×10^{-5} s^{-1}. The first step of splicing, the N-S acyl shift, was fast in comparison, with a pseudo-first-order rate constant of DTT-induced N-terminal cleavage of 1.0×10^{-3} s^{-1}. Preincubation experiments suggest that intein association is even faster. On the other hand, the rate constant of C-terminal cleavage, that is, asparagine cyclization coupled to peptide bond cleavage, was 1.9×10^{-4} s^{-1}. These data suggest that, for the *Ssp* DnaE intein, the N-S acyl rearrangement proceeds more rapidly than asparagine cyclization, which could serve to ensure that the steps of splicing proceed in order. Further detailed kinetic analysis of inteins and modified inteins could help determine how the intein catalyzes and coordinates the individual chemical steps of splicing.

6
Relationship of Inteins with Introns and Homing Endonucleases

Inteins and introns both interrupt the coding sequence of genes. As with inteins, group I and group II introns can catalyze their own excision from and the religation of flanking sequences. However, although inteins are excised posttranslationally, introns are excised at the RNA level. Like protein splicing, the splicing of introns from precursor RNA consists of a series of transesterification reactions. However, the self-splicing of introns *in vivo* is often inefficient in the absence of protein cofactors. Over 80% of inteins are interrupted by homing endonuclease domains, and many introns contain open reading frames outside of their core domains that encode homing endonucleases.

Homing endonuclease domains interrupt the majority of known inteins and are usually members of the dodecapeptide (LAGLI-DAG) family. The endonuclease domain of the *Sce* VMA intein can mediate intein homing. It cleaves at the intein insertion locus of an intein-less allele of the *Sce VMA* gene during meiosis and converts the allele lacking the intein into one containing an intein. However, the endonuclease is not required for protein-splicing activity. The crystal structure of this intein shows that it is a two-domain protein, with one domain responsible for protein-splicing activity and the other for endonuclease activity. The wide genetic distribution of mini-inteins that lack homing endonucleases suggests that the homing function may have evolved early and that modern mini-inteins lost their endonuclease domains.

The homing ability of inteins due to the endonuclease domain may explain some interesting aspects of intein distribution. For instance, few inteins are found in eubacteria aside from those in the mycobacteria and cyanobacteria. This could be explained by the fact that homing events have not been found to occur in *E. coli*. Another strange case involves the relationship of the DnaB inteins found in *Synechocystis* sp. PCC6803 and in *Rhodothermus marinus*. The DnaB inteins have 54% sequence identity and are inserted at the same site in the host protein, but the codon usage in the *R. marinus* intein is very different from the codon usage in the extein. If this is the result of homing by the same intein, it is curious how it could occur between such unrelated organisms. A third example is that the host proteins can share greater sequence similarity than the inteins. The VMA inteins in *Candida tropicalis* and *S. cerevisiae* are only 37% identical, whereas the host proteins are 88% identical. It would seem unlikely that unrelated inteins would invade the same gene if there were not some role for protein splicing that exerts genetic pressure to maintain the intein.

It is unclear if inteins or introns are more than merely parasitic DNA elements. Inteins usually interrupt conserved domains and introns are usually inserted at domain boundaries, suggesting that they might serve a regulatory function. The most likely case for possible gene regulation by an intein would seem to be the naturally split DnaE inteins, which could play a role in regulating DNA replication.

7
Relationship of Protein Splicing with Other Forms of Protein Autoprocessing

7.1
Bacterial Intein-like Domains

Bacterial intein-like domains (BILs) have been discovered in a wide range of bacterial

species. The BILs have more conserved sequence motifs than inteins, and are inserted into variable regions of their host proteins. There are two major categories of BILs: the A-type BILs contain the conserved intein sequence blocks, but mostly lack a C-terminal nucleophile, and the B-type BILs lack intein motifs C1 and C2, but usually have a nucleophilic residue at their penultimate positions.

A-type BILs have been shown to facilitate protein splicing as well as C-terminal cleavage reactions. An interesting case is an A-type BIL from *Clostridium thermocellum*, which facilitates proteins splicing, although it has a C-terminal alanine. This suggests that the BIL might splice via an alternative mechanism in which an N-S acyl rearrangement at the N-terminal splice junction and asparagine cyclization coupled to peptide bond cleavage at the C-terminal splice junction occur independently, and the free amino group of the C-extein's N-terminus then attacks the linear ester, resulting in ligation of the exteins (See Fig. 4). To date, B-type BILs have not been shown to facilitate protein splicing, but some can undergo N- and C-terminal cleavage reactions.

7.2 Hedgehog Proteins

Inteins and hedgehog proteins have many similarities, including amino acid sequence, three-dimensional structure, and catalytic function. Hedgehog proteins are involved in cell patterning during metazoan development, and disruption of the hedgehog-signaling pathway can lead to developmental disorders and tumorigenesis. They are found in almost all metazoans, whereas inteins are found only in unicellular organisms.

Hedgehog proteins, like inteins, undergo posttranslational autoprocessing. The *Drosophila* hedgehog protein was first shown to generate two protein domains from one larger protein precursor. The mechanism of this self-cleavage is similar to that of intein-mediated protein splicing (See Fig. 5). First, an N-S acyl rearrangement of the peptide bond between a conserved Gly-Cys sequence results in a thioester intermediate. Next, a transesterification between the 3β-hydroxyl of cholesterol and the newly formed thioester results in peptide bond cleavage and conjugation of the upstream fragment with cholesterol. In analogy with the role of exteins in protein splicing, the upstream signaling fragment is not required for autoprocessing, as hedgehog self-cleavage can occur in a foreign protein context.

HINT domains also occur in *Caenorhabditis elegans*, and are called *Groundhog* and *Warthog*. Although one of these HINT domains undergoes cleavage near the expected site if expressed in cultured *Drosophila* cells, the polypeptides flanking the HINT domain are dissimilar from those in the hedgehog proteins, which suggests that they may function differently in autoprocessing and cell signaling.

It is likely that the hedgehog proteins and inteins share a common ancestor. There is significant amino acid sequence homology between inteins and the autoprocessing domain of hedgehog proteins. In addition, the *Drosophila* hedgehog protein shares structural homology with intein domains. It has been suggested that inteins evolved from this common ancestor and propagated as a result of the invasion of a homing endonuclease. The hedgehog proteins may have lost the ability to splice

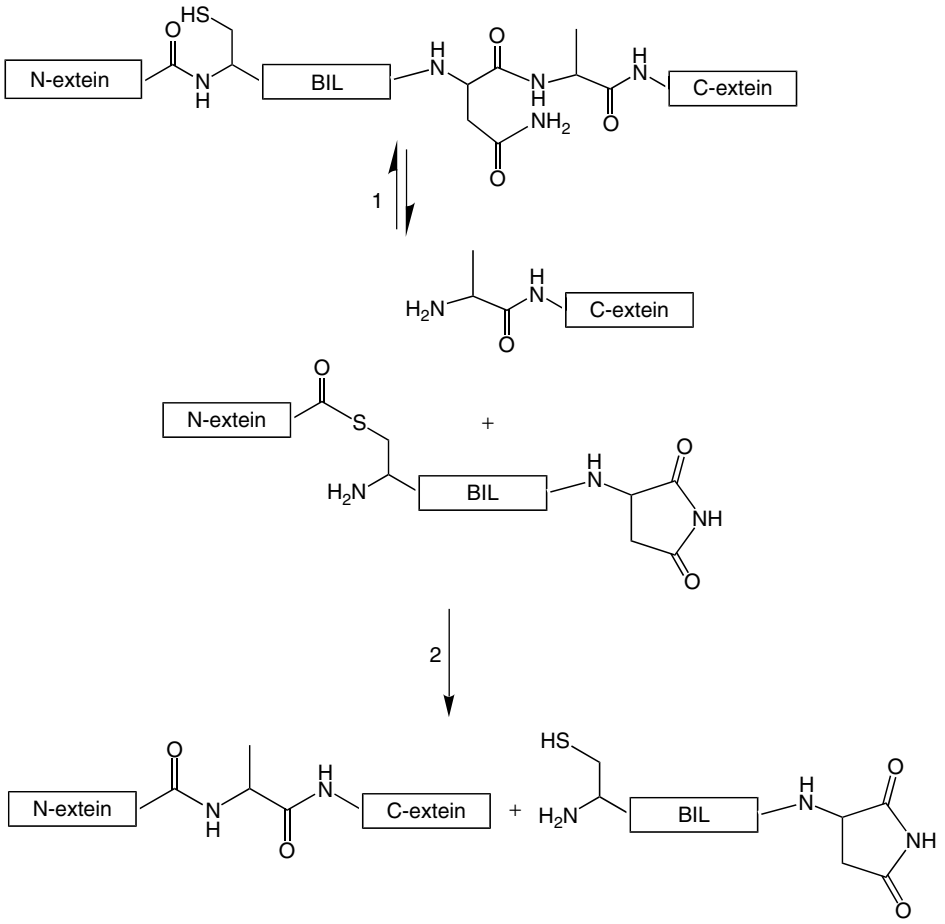

Fig. 4 Proposed alternate mechanism for splicing of a BIL without a C-terminal nucleophile.

while retaining the ability to facilitate an N-S acyl shift.

7.3 Pyruvoyl Enzyme Autoprocessing

A class of decarboxylases and reductases use a covalently linked pyruvoyl moiety as a prosthetic group instead of pyridoxal phosphate cofactors. In both histidine decarboxylase and aspartate decarboxylase, the pyruvoyl moiety is the result of self-catalyzed processing. Although there is no sequence or structural homology to inteins, the reaction is initiated by an N-O acyl rearrangement (See Fig. 5). A vestige of this reaction is seen in the crystal structure of *E. coli* aspartate decarboxylase. The precursor protein, π, is a tetramer, but only three subunits undergo processing. Autoprocessing is initiated by an N-O acyl rearrangement of the peptide bond between Gly24 and Ser25. The presence of an ester intermediate is suggested by the electron density of the unprocessed subunit.

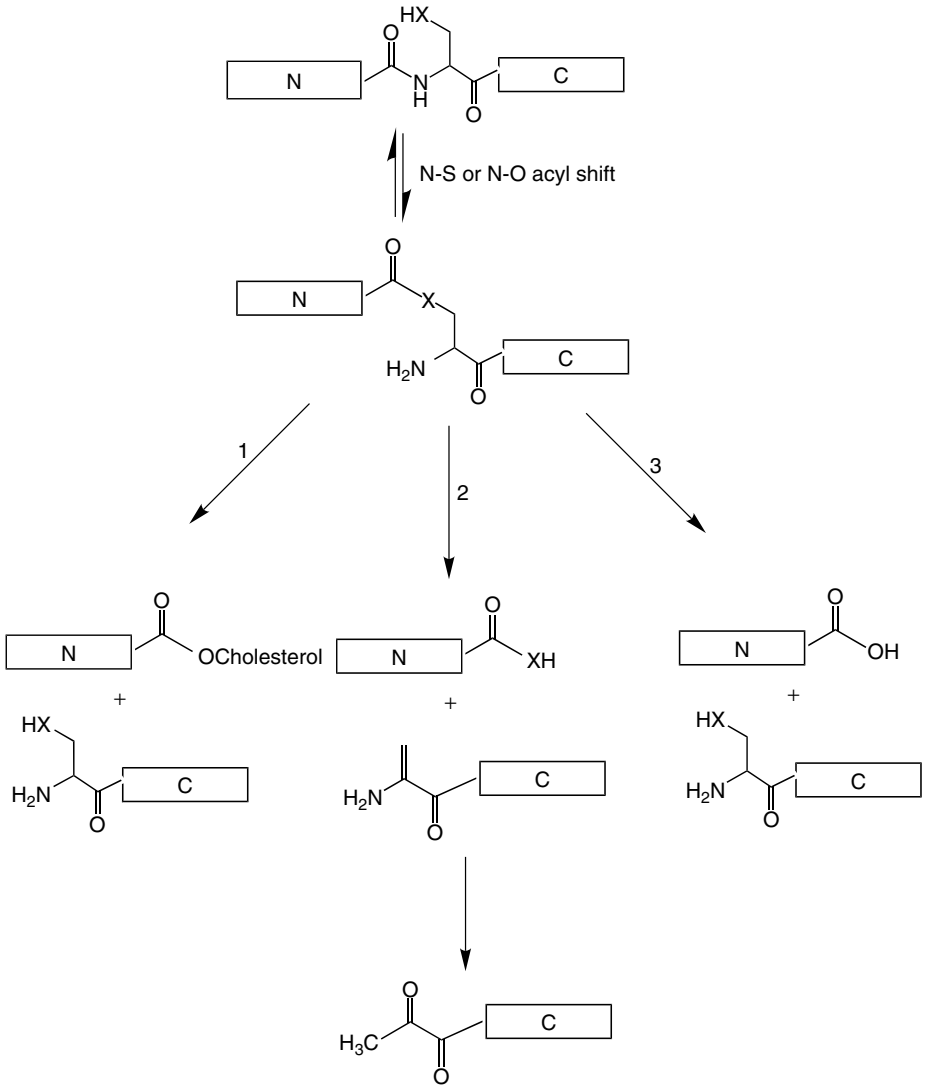

Fig. 5 Related forms of autoprocessing. Following an N-O or N-S acyl shift, the ester can be resolved by (1) transesterification with cholesterol as in hedgehog autoproteolysis; (2) β-elimination following by hydrolysis, as in pyruvoyl enzyme formation; or (3) hydrolysis as in N-terminal nucleophile or nucleoporin autocleavage. ''N'' and ''C'' in the boxes indicate the N- and C-terminal domains respectively.

Instead of the second transesterification reaction of inteins or hedgehog proteins, the breakdown of the ester is facilitated by β-elimination, followed by hydration to a carbinolamine and elimination of ammonia to form an N-terminal pyruvoyl group. As with some inteins, the position of the N-O equilibrium may be affected by catalytic strain, in this case by the presence of a tight

turn immediately preceding the scissile bond.

7.4 N-terminal Nucleophile Hydrolases

N-terminal nucleophile hydrolases, such as penicillin acylase, glutamine PRPP amidotransferase, and the proteosome are activated by cleavage of the peptide bond upstream of the catalytic residue to generate a catalytic subunit from a larger, inactive precursor. Direct evidence for intramolecular processing in this class of structurally related enzymes exists for glycosylasparaginase from *Flavobacterium meningosepticum* (*Fme*). Active glycosylasparaginase hydrolyzes the β-*N*-glycosidic bond between asparagine and *N*-acetylglucosamine in asparagine-linked glycans. Activation of the enzyme initiates with an N-O acyl rearrangement. In place of the transesterification reaction found with inteins, the ester is hydrolyzed to form two protein segments. The discovery that free glycine inhibits autoprocessing allowed the detection of a thioester intermediate by cleavage with neutral hydroxylamine in a Thr1Cys glycosylasparaginase mutant. Although there is no structural or evolutionary relationship between inteins and glycosylasparaginase, it is possible that glycosylasparaginase has also adopted conformational strain as a means to promote an amide to ester rearrangement. The crystal structure of the *Fme* glycosylasparaginase reveals a tight turn involving the scissile bond, resulting in a deviation from planarity of the peptide bond immediately downstream of the scissile bond by more than 20°, as well as deviation of the backbone τ angles by more than 9°. The distortion is stabilized by interaction of the side chain of the N-1 aspartic acid residue (Asp151) with Thr203 and the catalytic Thr152. Perhaps the release of this steric strain favors formation of the ester intermediate.

7.5 Nucleoporins

Another example of protein autoprocessing involves the self-catalyzed cleavage of the yeast nucleoporin Nup145. The nuclear pore complex is responsible for many aspects of cellular function, including the exchange of protein and RNA between the nucleoplasm and the cytosol. Nup145p is a 145-kDa protein that is posttranslationally processed into a 65-kDa N-terminal domain and an 80-kDa C-terminal domain. The C-terminal domain functions as part of a nucleoporin complex that controls mRNA export and nuclear architecture. The function of the N-terminal fragment is not clear, but it is improperly localized if separately expressed from the C-terminal fragment. Thus, Nup145p autoprocessing plays a regulatory role in the cellular localization of essential proteins. The autoprocessing is initiated by an N-O acyl rearrangement that results in hydrolysis of the peptide bond between phenylalanine and serine in a conserved His-Phe-Ser motif (See Fig. 5). Deletion of the first 712 residues of Nup145p does not eliminate autoprocessing, which suggests that the information required for processing is located mostly in the C-terminal domain. In the crystal structure of human nucleoporin Nup98, hydrogen bonding is evident between the histidine and serine of the conserved triad. Although there is no evidence of catalytic strain, there is tight anchoring of the side chain of the conserved phenylalanine of the conserved triad in a hydrophobic pocket as well as β-strand interactions downstream of the

scissile bond, which may suggest the use of constrained geometry in the promotion of the amide–ester rearrangement. Although nucleoporin autoprocessing and protein splicing share the same first step, there is no structural or sequence homology between these autoprocessing domains.

8 Inteins in Biotechnology

8.1 Self-cleavable Affinity Tags

One of the first applications developed that takes advantage of protein-splicing elements was the use of inteins modulated by mutation for use in protein purification. Protein purification is often facilitated by the use of affinity tags, but it is sometimes necessary to remove these domains from the protein of interest. Traditionally, this is done using a protease that must then be separated from the target protein. However, if the affinity tag is fused to an intein, it is possible to cleave the intein-affinity tag fusion from the target protein, using either N-terminal or C-terminal cleavage uncoupled from the overall protein-splicing reaction (See Fig. 6).

The first affinity tag purification scheme developed uses a modified form of the *Sce* VMA intein that can be induced to cleave at the intein N-terminus. Precursor protein accumulates if the C-terminal intein asparagine residue is mutated to alanine, preventing the final step of splicing. If the target protein is used as the N-extein and an affinity tag as the C-extein, the precursor can be purified using an affinity resin. The protein target can then be eluted by initiation of N-terminal cleavage by added thiol. If cysteine is used, it can be incorporated into the target protein at its C-terminus by essentially irreversible S-N acyl rearrangement after cleavage. Protocols using mini-inteins can allow purification of larger target proteins. N-terminal cleavage of the *Ssp* DnaB mini-intein can be induced by raising the pH to 8.0 or the temperature to 25 °C, eliminating the need for added thiols.

Alternatively, the target protein can be fused to the intein C-terminus, and the N-extein can be used as the affinity tag. Purification is accomplished by inducing C-terminal cleavage via asparagine cyclization. One would expect higher levels of expression of soluble fusion proteins in such a system, in which a soluble *E. coli* protein such as maltose-binding protein can be used as the N-terminal domain. The first such system described uses a *Sce* VMA intein modified by mutation such that C-terminal cleavage only occurs after N-terminal cleavage is induced by the addition of exogenous thiol. However, in this case the N-extein peptide coelutes with the C-extein target and added thiol. Later systems use modified inteins for which C-terminal cleavage does not require prior cleavage at the intein N-terminus and can be induced by a change in pH or temperature.

8.2 Protein Ligation

Protein semisynthesis in aqueous solution in the absence of enzymes has been a long-standing goal in synthetic chemistry. Two methods of protein semisynthesis are native chemical ligation and expressed protein ligation.

The native chemical ligation scheme developed by Tam and coworkers involves the ligation of a peptide with a C-terminal thioester to a peptide with an N-terminal

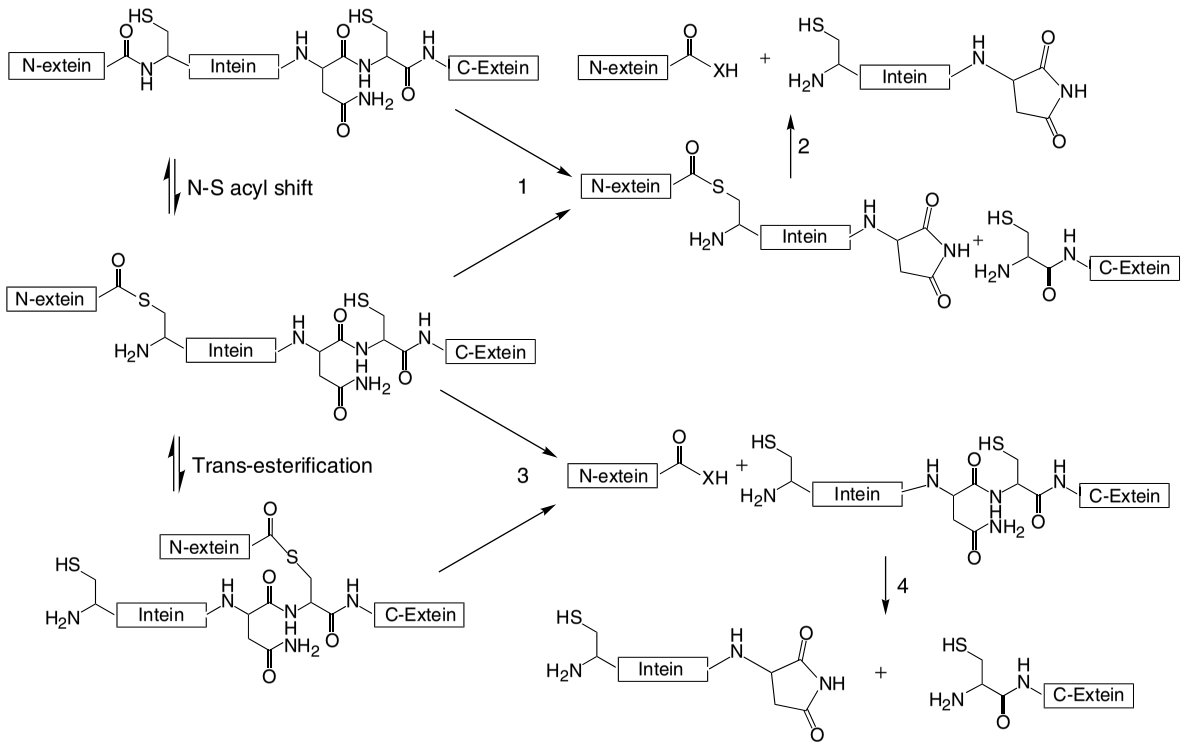

Fig. 6 Side reactions that are manipulated in intein-based protein purification and ligation systems. (1) Premature asparagine cyclization of the precursor or linear ester can lead to C-terminal cleavage, possibly followed by (2) hydrolysis or thiolysis at the N-terminal splice junction. (3) Hydrolysis or thiolysis of the linear or branched esters can lead to N-terminal cleavage, possibly followed by (4) cyclization of asparagine at the C-terminal splice junction coupled to peptide bond cleavage.

cysteine (mediated by a trialkylphosphine and an alkylthiol), or the ligation of a peptide with a C-terminal thiocarboxylic acid to a peptide with an N-terminal β-bromo amino acid at low pH. Another method, developed by Kent and coworkers, ligates a peptide with a C-terminal thioester and a peptide with an N-terminal cysteine and proceeds in the presence of Ellman's reagent. However, the bimolecular nature of both methods results in a relatively slow rate of ligation. The methods also require a cysteine residue at the junction of the ligated peptides as well as the synthesis of the N-terminal segment, which limits the size of the protein target. However, other methods avoid the requirement for the cysteine residue. For instance, in ''conformationally assisted protein ligation,'' the ligation of ribonuclease S with the S-peptide between alanine and serine is facilitated by the prior refolding of the two fragments. Native chemical ligation between a thioester and a 2-mercaptobenzylamine-linked peptide results in a peptide bond without the need for cysteine, albeit with *o*-benzylmercaptoamine in the product. Another method uses a phosphinobenzenethiol to facilitate native chemical ligation between a peptide with a C-terminal thioester and a peptide with an N-terminal azide, yielding a native peptide with no requirement for cysteine or affinity between the peptide targets. However, this method remains limited to the ligation of small peptides because of the need to synthesize the thioester-containing peptide.

The semisynthesis of proteins with building blocks generated using inteins presents a great advantage over the synthetic peptides used in native chemical ligation procedures. This ''expressed protein ligation'' was first described using the *Sce* VMA intein with the target protein as the N-extein. The target protein is purified with a C-terminal thioester via N-terminal cleavage of the intein induced by thiophenol. It is then ligated to a peptide with an amino-terminal cysteine. A more efficient procedure was developed using the *Mxe* GyrA mini-intein, using 2-mercaptoethanesulfonic acid to induce N-terminal cleavage. Expressed protein ligation methods of this kind also employ the *Mth* RIR1 mini-intein and the *Ssp* DnaB mini-intein. However, these methods require the use of a synthetic peptide containing an N-terminal cysteine. Two procedures were developed to avoid the need for a synthetic peptide. In one, factor Xa is used to cleave a target peptide upstream of a cysteine residue. The second uses controlled intein C-terminal cleavage to generate a cleaved C-extein with an N-terminal cysteine. Recent applications include intein-mediated biotinylation of proteins, conjugation of an oligonucleotide to a recombinant protein, and semisynthesis of a protein with β-amino acids.

Protein splicing in trans is an essentially unimolecular method of protein ligation. It was originally used to ligate maltose-binding protein to paramyosin or a tetrapeptide using the *Psp*-GBD-Pol intein or to a His-tag-containing domain using the *Mtu* RecA intein. Using a synthetic peptide as the C-terminal fragment of the *Mtu* RecA intein, peptides containing synthetic probes or nonnatural amino acids can be ligated to target proteins. However, these methods are limited by the need for joint denaturation and renaturation. The discovery of a naturally split intein, the *Ssp* DnaE intein, opened the possibility of protein ligation *in vitro* by protein trans-splicing without prior denaturation, and can be applied to proteins that cannot be reversibly denatured. The discovery of ''conditional'' protein splicing

in trans, by which association and therefore subsequent splicing of the split *Sce* VMA intein is induced by the fusion of complementary components of a protein dimerization domain to the intein segments, could allow regulation of protein ligation *in vitro* and *in vivo*.

The discovery of intein-mediated protein ligation in trans has led to a number of interesting applications. For instance, each fragment of a split *Sce* VMA intein was fused to a fragment of green fluorescent protein (GFP). Although the intein fragments interact only weakly, if fused to proteins that interact strongly, they associate properly and splice to yield functional GFP. This system was used *in vivo* to measure protein–protein interactions. In another example, split *Ssp* DnaE fragments, each fused to fragments of 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS), yields a reconstituted, although not spliced, enzyme. The reconstituted enzyme rescues the growth of *E. coli* cells with a depletion of the *EPSPS* gene if cultured in the presence of glyphosate. Herbicide-resistant acetolactate synthase was also split and fused to the two segments of the *Ssp* DnaE intein, which mediates splicing of the acetolactate synthase as well as resistance to valine growth inhibition in *E. coli*. Trans-splicing of EPSPS mediated by the split *Ssp* DnaE intein is also observed in the chloroplast of *Nicotiana tabacum* when a gene encoding for N-terminal intein-EPSPS fusion was integrated into the nuclear DNA and a gene encoding for the C-terminal intein-EPSPS fusion was integrated into the chloroplast genome. These transgenic plants also show an increased resistance to glyphosate. Trans-splicing of split β-glucuronidase in *Arabidopsis* using the *Ssp* DnaE intein has also been observed.

8.3 Protein Cyclization

An interesting use of inteins involves the cyclization of proteins by native chemical ligation, expressed protein ligation, and protein trans-splicing. Cyclized proteins are resistant to exoproteases and useful in the study of protein folding dynamics.

Two methods for protein cyclization have been developed on the basis of native chemical ligation. In one, an unprotected peptide is synthesized with an N-terminal cysteine and a C-terminal thioester on a Boc-Gly-aminomethyl-polystyrene resin with a thioester ''handle.'' The thioester is derivatized with Ellman's reagent and the cyclic peptide is formed in the presence of thiophenol. Another method involves the cyclization of the 47-residue WW domain from human Yes kinase-associated protein. The protein was synthesized with a C-terminal thioester and an N-terminal cysteine, and allowed to fold. The cyclization proceeds whether the protein is folded or not, but the cyclization is an order of magnitude faster when the protein is folded because the N- and C-termini of the protein are in closer proximity.

The size limitations of protein cyclization are largely eliminated by the development of expressed protein ligation protocols. One group fused the N-terminus of a target protein to a modulated *Ssp* DnaB intein and the C-terminus of the target protein to the *Mxe* GyrA intein. Cleavage at the N-terminus of the target protein is initiated by pH-induced asparagine cyclization of the DnaB intein. This is followed by cleavage at the C-terminus of the target protein by addition of 2-mercaptoethanesulfonic acid, resulting in a target protein with an N-terminal cysteine and a C-terminal thioester, which

can either cyclize or polymerize. In another method, an SH2 domain is cyclized by fusion to the N-terminus of the *Sce* VMA intein. An N-terminal cysteine is revealed by factor Xa cleavage and reacts with the thioester at the N-terminal splice junction to liberate cyclized protein. A similar method was used to cyclize β-lactamase that is more stable to heat denaturation than the linear form.

Protein cyclization based on trans-splicing was first developed using the naturally split *Ssp* DnaE intein *in vivo*. The C-terminal segment of the DnaE intein is fused to the target protein at its N-terminus, and the N-terminal segment of the intein is fused to the target at its C-terminus, such that protein splicing yields a cyclized product. This method is called *SICLOPPS*, or split intein-mediated circular ligation of peptides and proteins. A similar system was used to circularize maltose-binding protein *in vivo* as well as *in vitro*. A split version of the *Pfu* Pol1 intein can cyclize GFP *in vivo*, which denatures at half of the rate of uncyclized GFP. Intein-mediated cyclization can be used to generate cyclic peptide libraries in cells to screen for bioactive compounds.

8.4 Screening Systems Utilizing Inteins

Inteins have been used in the design of genetic screening systems. In one such system, a plasmid-carried gene encoding for aminoglycoside phosphotransferase (aph) was interrupted with the *Mtu* RecA intein, such that cell growth in the presence of kanamycin is dependent on efficient protein splicing. This aph-intein fusion was used to screen for open reading frame insertions into the DNA sequence coding for the intein. Belfort and coworkers created a screening system based on the splicing of thymidylate synthase (TS) interrupted by the *Mtu* RecA intein. In *thyA E. coli*, one can select for protein splicing by growth in the absence of thymine, which would require protein splicing to generate a complementary TS, and select against protein splicing in the presence of thymine and a DHFR inhibitor, which would be lethal in the presence of spliced, complementary TS. This system was used to define the minimal size of a functional intein and to select for an intein that can facilitate pH-dependent C-terminal cleavage.

Temperature-sensitive intein mutants were selected using a system based on the *Mxe* GyrA intein. Splicing of the split GyrA protein results in cell death in the presence of quinoline-related gyrase inhibitors, so this system could be used to select for inhibitors of protein splicing by coupling cell survival to efficient splicing. Protein-splicing inhibitors could also be detected using a system based on the cytotoxicity of the ccdB protein. N-terminal fusion of lacZα to the cell death domain ccdB does not emeliorate the cytotoxicity of ccdB, but the insertion of the *Mtu* RecA intein between lacZα and ccdB does ablate ccdB function. Therefore, inhibition of protein splicing can be coupled to cell survival. Finally, the fluorescence of GFP interrupted by the *Mtu* RecA intein is dependent on removal of the intein by protein splicing, and this could be used as a colorimetric assay for protein-splicing inhibition.

9 Perspective

Protein splicing was first discovered in 1990. Since that time, the chemical steps

of this process have been defined, and a variety of clever and useful biotechnology applications have been developed. However, many questions and interesting avenues of inquiry remain. For instance, the means by which inteins facilitate and coordinate each step of splicing remain largely unanswered. It is also unclear if inteins are merely molecular parasites, or if they play a role in the regulation of gene expression. If so, inhibitors of protein splicing could be designed and used to dissect this biological role. Inteins could also serve as drug targets, as one could imagine that the inactivation of such interrupted exteins as the RecA or DnaB proteins of *Mtu* could have antimicrobial effects. The majority of the studies of protein splicing have been done with foreign proteins as the exteins and *in vitro* or in *E. coli*, which does not have inteins, so it will be interesting to study the splicing of inteins in their natural hosts and extein contexts. Finally, it is interesting that inteins and hedgehog domains have considerable sequence and structural homology, but that inteins are found only in unicellular organisms and do not have an identified function, whereas hedgehog proteins are found in most metazoans and play an essential role in embryonic development. Perhaps the recently discovered bacterial intein-like domains will serve as an evolutionary link between these autoprocessing domains.

Keywords

Active Site
Part of an enzyme molecule made up of amino acid residues, and involved in substrate binding and catalysis.

Anomalous Diffraction
Diffraction of X-rays near the absorption edge of a scattering atom, where a phase shift occurs and the atomic scattering factor becomes a complex quantity; This phenomenon is exploited in phasing X-ray diffraction data.

Isotope Labeling
Introduction of ^{13}C, ^{15}N and other nonradioactive isotopes into a protein for structure determination by nuclear magnetic resonance (NMR) spectroscopy.

Phasing
Reconstitution of the phase relations of diffracted X-rays as part of a crystal structure analysis, using anomalous diffraction and other techniques.

Posttranslational Modification
Covalent modification of a protein molecule after translation by phosphorylation, glycosylation, acetylation and so on. This is rare in prokaryotic proteins, and common in proteins from eukaryotes.

Protein Disorder
Lack of defined three-dimensional structure in segments of proteins or complete proteins in the absence of stabilizing binding partners.

Protein Domain
Compact folding unit of a protein, recognizable on the sequence and/or three-dimensional structure level.

Protein Fold
Recurrent pattern of three-dimensional structure in a protein or protein domain. There are far fewer protein folds than sequences or sequence families.

Selenomethionine
Nonnatural amino acid that can be incorporated into proteins by gene technology in place of methionine. Its selenium atom is used as an anomalous scatterer for phasing the X-ray diffraction pattern.

Structural Genomics
Large-scale project to determine the shapes of all proteins and other important biomolecules encoded by the genomes of key organisms.

Structural Proteomics
Large-scale project to determine the shapes and functions of all proteins encoded by the genomes of key organisms.

Synchrotron Radiation
Electromagnetic radiation emitted by subatomic particles (electrons or positrons) traveling at high velocity in storage rings. X-rays produced at synchrotrons are used in crystal structure determination.

Developments in the high-throughput analysis of protein structure have been primarily driven by worldwide structural genomics initiatives that are aimed at determining the three-dimensional structures of all proteins and other important biomolecules encoded by the genomes of key organisms. Structural genomics requires a large number of procedural steps in order to convert sequence information into a three-dimensional structure; this has led to new high-throughput methods for protein production, characterization, and structure determination. Over the past decade, the most notable technological advances have been in the fields of X-ray crystallography and NMR – the principal tools of structural genomics – which have facilitated high-throughput, rapid, and cost-effective structure determinations. In recent years, these developments have resulted in an exponential increase in the number of structures being deposited in the Protein Data Bank (PDB; http://www.rcsb.org/pdb/), in which the total number currently exceeds 30 000. Major developments in the fields of bioinformatics, protein production, and structure determination, and the impact of these on high-throughput protein structure analysis will be discussed in what follows.

1 Bioinformatics

Primary sequence analysis, such as similarity searches against protein sequence databases, protein domain architecture determination, identification of specialized local structural motifs, and prediction of protein structure are possible with a variety of homology-based modeling methods (Fig. 1). Sequence database searches are particularly useful in selecting targets for structural genomics initiatives and, where possible, generating homologous probes for determining structures by the molecular replacement method. For example, the Web-based program 3D-PSSM (http://www.sbg.bio.ic.ac.uk/~3dpssm/) is a fast method for predicting the protein fold from the primary amino acid sequence, and SWISS-MODEL (http://swissmodel.expasy.org/) is a fully automated protein structure homology-modeling server.

1.1 Structure-to-function Approaches

There are a number of bioinformatics resources available that are aimed

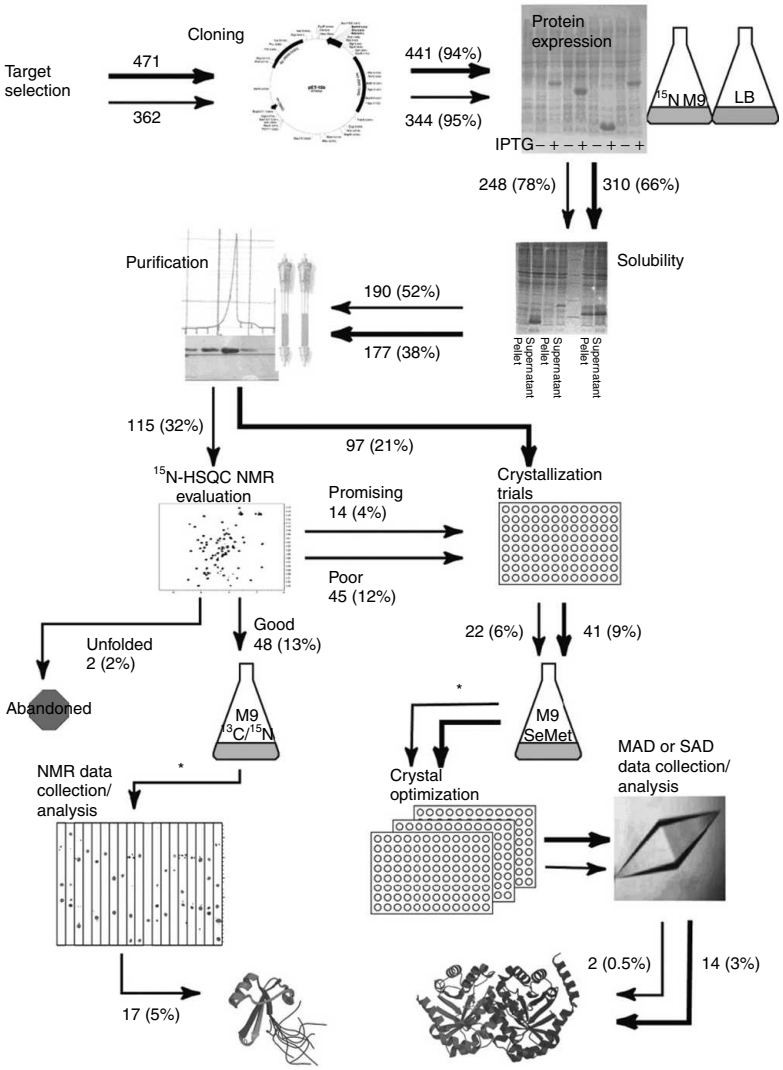

Fig. 1 Schematic flow diagram of the strategies employed in structural genomics initiatives, using *Methanobacterium thermoautotrophicum* as an example. The number of protein targets after each step and the percentage relative to the number of starting targets are indicated in brackets. Thin arrows and italicized numbers are for smaller molecular-weight proteins, and wide arrows and bold numbers are for larger molecular-weight proteins. Diagram taken from Yee, A., Pardee, K., Christendat, D., Savchenko, A., Edwards, A.M., Arrowsmith, C.H. (2003) Structural proteomics: toward high-throughput structural biology as a tool in functional genomics, *Acc. Chem. Res.* **36**, 183–189. Picture with permission from Prof. Cheryl Arrowsmith.

at identifying a protein's biochemical function from its three-dimensional structure (Fig. 2). For example, Dali (http://www2.ebi.ac.uk/dali) and VAST (Vector Alignment Search Tool; http://www.ncbi.nlm.nih.gov:80/Structure/VAST/vastsearch.html) offer Web-based servers for automatically comparing the fold of a newly determined structure against known folds, as represented by the protein structures in the PDB. Such comparisons can often reveal striking similarities between proteins that are not evident from sequence analysis alone, and that can provide important insights into biological function even in the absence of any other biochemical or functional data. However, computer-based approaches fail to assign functions to proteins that adopt novel folds. Enzymes are a notable exception to this rule, because the groupings of residues constituting their active sites tend to be highly conserved in their spatial disposition even in cases where there is no overall similarity in sequence or fold. For example, the relative positioning of the Ser-His-Asp catalytic triad of the serine proteases is highly conserved even when found in protein structures adopting different folds. Hence, screening a new protein structure against a database of enzyme active-site templates such as PROCAT (http://www.biochem.ucl.ac.uk/bsm/PROCAT/PROCAT.html) can be used for detecting key functional residues. The spatial patterns of residues can be automatically generated using various techniques including graph theory (ASSAM) and "fuzzy pattern matching" (RIGOR). Alternative approaches to identifying enzymes

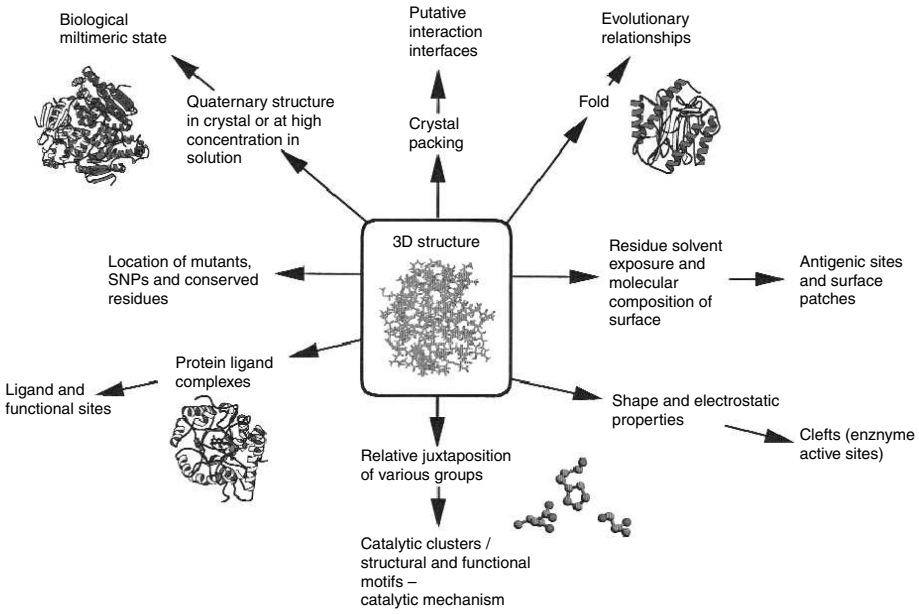

Fig. 2 Summary of the information deriving from the three-dimensional structure of a protein, relating to its biological function. Taken from Thornton, J.M., Todd, A.E., Milburn, D., Borkakoti, N., Orengo, C.A. (2000) From structure to function: approaches and limitations, *Nat. Struct. Biol.* **7**(Suppl.), 991–994.

on the basis of their three-dimensional structure and predicting their functions, have recently been reported. Here, a vector machine-learning algorithm is used, based on the secondary structure of proteins the propensities of amino acids, and surface properties, in order to discriminate enzymes from nonenzymes. Another approach analyses protein surface charges to identify conserved residues that can serve as catalytic sites. Once a general class of biochemical function of a protein has been proposed, experimental screening of enzymatic activity can be used to derive the precise biochemical function. For example, after the structure determination of BioH (an enzyme involved in biotin biosynthesis in *E. coli*) the protein structure was screened against a library of enzyme active sites, a Ser/His/Asp catalytic triad was identified, and subsequent hydrolase assays showed BioH to be a carboxylesterase.

1.2 Identification of Disordered Regions in a Protein

The occurrence of regions in proteins that lack any fixed tertiary structure is increasingly being observed in structural studies. These disordered regions or ''random coils'' are inherently flexible and are involved in a variety of functions, including the modulation of the specificity/affinity of protein-binding interactions, activation by cleavage, and DNA recognition. During the target selection process, it is important to consider any intrinsic protein disorder, because it can often lead to problems with the expression of protein-coding genes, protein stability, purification, and crystallization. PONDR, DisEMBL, and GlobPlot are useful tools for predicting potential disordered regions within a protein sequence that can be used to help design constructs corresponding to globular proteins or domains. PONDR (Predictor of Naturally Disordered Regions; http://www.pondr.com) and DisEMBL use methods based on artificial neural networks, whereas GlobPlot (http://globplot.embl.de) relies on a novel, propensity-based disorder-prediction algorithm. These methods can also be used to predict inherently flexible regions in protein sequences. For example, PONDR predicted that the linker between the DNA-operator-binding central domain of the transcriptional regulator KorB (KorB-O) and the KorB dimerization domain (KorB-C) is flexible, which was indeed observed in crystal structures and is thought to facilitate complex formation on circular plasmids (Fig. 3).

1.3 Protein-ligand Complexes

Protein-ligand complexes are the most useful in terms of providing functional information, because they reveal the nature of the ligand, the site at which it is bound to the protein, the location of the active site, and of the catalytic machinery (if the protein is an enzyme). There are several examples of structural analyses in which an unexpected protein-bound ligand or cofactor derived from the cloning organism was discovered. For example, the structure of the trimeric human protein p14.5 was found to have picked up benzoate molecules from the crystallization buffer at its inter-subunit tunnels, which most likely mark a hydrolytic active site (Fig. 4). When such data are available at high resolution, proposing a biological function for the protein can be relatively straightforward, because these data identify the nature of the ligand, the

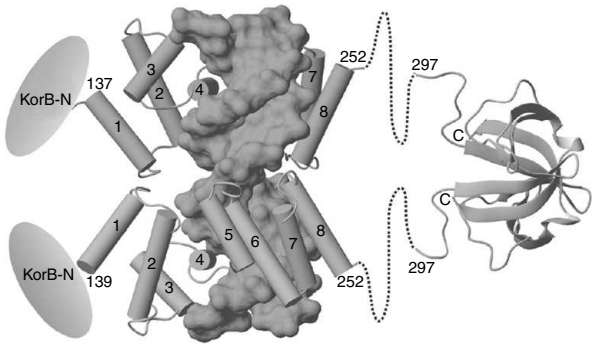

Fig. 3 Natively disordered regions in the bacterial transcriptional regulator and partitioning protein KorB. The KorB DNA-binding domains (KorB-O, center) are connected by flexible linkers to N-terminal domains of unknown structure and function (KorB-N, left), and the KorB dimerization domains (KorB-C, right). Picture taken from Khare et al., 2004.

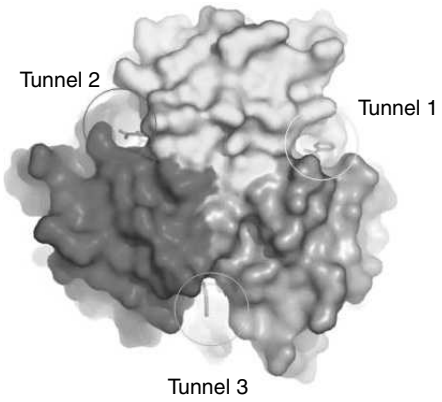

Fig. 4 Crystal structure of the trimeric human protein, hp14.5. Benzoate molecules picked up from the crystallization buffer bind in the inter-subunit tunnels and mark putative hydrolytic active sites (Manjasetty et al., 2004). Picture with permission from Dr. B.A. Manjasetty.

ligand-binding site, and the arrangement of catalytic residues from which a catalytic mechanism can be postulated.

2 Protein Production

Protein expression and purification play a central role in high-throughput protein structure analysis. Cloning using restriction enzymes is impractical for high-throughput approaches, because of the complications of selecting compatible and appropriate restriction enzymes for each cloning procedure, and the multiple steps of experimental refinement and treatment that must be performed. Therefore, high-throughput cloning requires procedures based on the polymerase chain reaction (PCR). High-throughput cloning and expression methods are now being developed in many laboratories, enabling the generation and testing of up to hundreds of DNA constructs for high-level expression in parallel, using rapid and

generic protocols. To generate expression vector clones, generic cloning systems can be used; the Gibco/Life Technologies GATEWAY™ system is one such example, streamlining the expression and cloning process by alleviating recloning steps and avoiding the use of restriction enzymes in the cloning and subcloning processes.

High-throughput approaches may rely on both prokaryotic and eukaryotic hosts. *Escherichia coli* expression systems are advantageous for many reasons, most notably because the overproduced protein is usually obtained without any posttranslational modification heterogeneity, and protein expression is cheaper and faster than with eukaryotic systems. However, it is not always possible to obtain soluble protein for many eukaryotic proteins, in particular, human proteins, by using the heterologous expression of eukaryotic genes, in which the codon usage for a cDNA could be suboptimal in *E. coli*. Furthermore, eukaryotic systems are necessary for the expression of proteins that require posttranslational modifications for their correct folding and activity. In situations in which a protein cannot be synthesized in *E. coli*, the eukaryotic yeasts (*Saccharomyces cerevisiae* and *Pichia pastoris*), baculovirus-infected insect cells, *Leishmania tarentolae,* and the cell-free wheat germ systems that have been developed for high-throughput approaches can be used. Furthermore, in these and other eukaryotic expression systems, the codon usage is closer to that in humans. The various merits of each system are discussed below.

2.1 Yeast

The yeasts *S. cerevisiae* and *P. pastoris* can be used for the routine production of recombinant proteins. More recently, *P. pastoris* has emerged as the preferred yeast, because of its strong, highly inducible promoter system resulting in higher yields of recombinant protein, stable genomic integration and posttranslational modifications, such as phosphorylation, which may be important for both the structure and function of some human proteins. In comparison with *S. cerevisiae*, the distribution and chain length of *N*-linked oligosaccharides are significantly shorter, and therefore this system represents a suitable alternative for the extracellular expression of human proteins. An additional advantage of the methylotrophic *P. pastoris* expression system is that it makes it possible to introduce ^{13}C label into recombinant proteins (by feeding ^{13}C-labeled methanol) for nuclear magnetic resonance (NMR) structural analyses.

2.2 Baculovirus–insect Cell

The recombinant baculovirus–insect cell expression system accomplishes most posttranslational modifications, including phosphorylation, *N*- and *O*-linked glycosylation, acylation, disulfide cross-linking, oligomeric assembly, and subcellular targeting, which may all be critical for the accurate production and function of human proteins. In contrast to bacterial expression systems, the recombinant baculovirus expression system usually produces soluble proteins without the need for induction or specific temperature conditions.

2.3 *Leishmania tarentolae* (Trypanosomatidae)

The use of the parasitic Trypanosomatidae species, *L. tarentolae*, as the host for

in vitro protein production has recently been reported, and can achieve high levels of protein expression. The Trypanosomatidae species of parasites naturally produce large amounts of glycoproteins, which is an advantage in the production of sialylated heterologous glycosylated proteins. Furthermore, given the natural auxotrophy of *L. tarentolae* for methionine, it has been suggested that such a system could prove to be useful for the production of selenomethionine-labeled proteins, for high-throughput X-ray crystallographic structure determination using single- or multiple-wavelength anomalous diffraction (SAD and MAD) phasing techniques.

2.4 Cell-free Expression Systems

Cell-free systems facilitate the parallel expression of many protein-coding genes, and are therefore suitable for high-throughput protein production. Obtaining the protein directly in a form suitable for X-ray crystallography or NMR spectroscopy is another prerequisite for high-throughput structure analysis. For the purpose of X-ray analysis, anomalous diffraction techniques (SAD or MAD) necessitate the substitution of methionine residues with selenomethionine. Additionally, NMR structure analysis often requires the labeling of proteins with ^{13}C and/or ^{15}N, which can be introduced through cell growth on media containing these isotopes in the form of ^{13}C-glucose and $^{15}NH_4Cl$. In this respect, the *E. coli* cell-free protein synthesis system of Kigawa et al. (1999) permits the straightforward incorporation of isotopes for NMR analysis. However, this system is not always suitable for the expression of some eukaryotic proteins and can result in aggregation, formation of insoluble inclusion bodies, and degradation of the expression product. Furthermore, in the case of multidomain proteins, which are found more often in eukaryotes, correct folding occurs more frequently in eukaryotic than in prokaryotic translation systems. Another limitation with the use of *E. coli* systems for high-throughput cell-free expression is that PCR-generated fragments are not transcribed and translated efficiently in these systems: contamination by the mRNA- and DNA-degradation enzymes originating from the cell decreases the stability of the templates and reduces yields. By contrast, in eukaryotic cell-free systems, the added mRNAs are stable for long periods of time, and therefore these systems overcome many of the limitations associated with *E. coli* cell-free systems. Furthermore, cell-free systems can produce high yields of correctly folded proteins and, unlike *in vivo* systems, facilitate the expression of proteins that would otherwise interfere with the host cell physiology. Recently, the synthesis and screening of gene products based on the cell-free system prepared from eukaryotic wheat embryos has been reported; this method bypasses many of the time-consuming cloning steps involved in conventional expression systems and lends itself to the high-throughput expression of proteins, using automated robotic systems.

3 Purification

Protein purification has also seen significant improvements because of the use of affinity tags fused to the protein of interest, so that it can be separated from the host cell proteins rapidly by using standardized purification schemes. N-terminal tags range from large tags, such as

glutathione-S-transferase (GST), maltose-binding protein (MBP), thioreductase, and the chitin-binding protein, to fairly small tags such as His_6, and various epitope tags. In some systems, the use of large tags can lead to the production of fusion products that are too large for high-level expression, but the use of such tags can improve the correct folding and stability of the overexpressed protein. His_6 is the most commonly used purification tag, because it is easier to incorporate into expression constructs and it allows a generic one-step purification using automated methods based on nickel-nitrilotriacetic acid (Ni-NTA) or other immobilized metal-affinity chromatography resins. The use of an additional C-terminal StrepII tag enables dual-affinity column purification, which ensures that only full-length gene products are separated. For crystallization to occur, it is generally agreed that the fusion tags must be removed, because they can introduce flexible regions into the protein, which can interfere with crystallization or lead to various forms of microheterogeneity. In a recent study, the compatibility of small peptide affinity tags with protein crystallization was assessed, in which the N-terminus of the chicken spectrin SH3 domain was labeled with a His_6 tag and a StrepII tag, fused to the N- and C-termini, respectively. The resulting protein, His_6-SH3-StrepII, comprised 83 amino acid residues, 23 of which originated from the tags (accounting for 23% of the total fusion protein mass). In contrast to the general consensus that the presence of affinity tags is detrimental in structural studies, this study demonstrated that the fused affinity tags did not interfere with crystallization or structure analysis, and did not change the protein structure. This suggests that, in some cases, protein constructs utilizing both N- and C-terminal peptide tags may lend themselves to structural investigations in high-throughput regimes.

4 Structure Determination by X-ray Crystallography

4.1 Crystallization

Crystallization is regarded as a major bottleneck in structure determination by X-ray crystallography and can be divided into two stages: coarse screening for initial crystallization conditions, followed by optimization of the conditions in order to produce diffraction-quality single crystals. The field of crystallization has recently been revolutionized by significant developments in automation, miniaturization, and process integration. These developments have led to the availability of robotic liquid-handling systems that are capable of rapidly and efficiently screening thousands of crystallization conditions, in which different parameters such as ionic strength, precipitant concentration, additives, pH, and temperature are altered. High-throughput screening begins with the automated preparation and/or reformatting of precipitant solutions into crystallization microplates. The latest nanoliter robotic liquid-dispensing systems are capable of dispensing very small drops (typically containing between 25 and 100 nL of protein), which reduces the amount of protein required for screening conditions and the overhead on protein production. Furthermore, smaller drops equilibrate faster than larger drops, leading to a more rapid appearance of crystals. The crystallization experiments are then regularly monitored using an imaging robot, and the collected images can either be analyzed visually

or by using automatic crystal recognition systems. HomeBase™ (The Automation Partnership, UK) represents an integrated system combining high-density plate storage and imaging.

A recent development in protein crystallization has been the use of a microfluidic system for crystallizing proteins, using the free-interface diffusion method at the nanoliter scale. This system is capable of screening hundreds of crystallization conditions in which droplets, each containing solutions of protein, precipitants, and additives in various ratios, are formed in the flow of immiscible fluids inside a polydimethylsiloxane (PDMS)/glass capillary composite microfluidic device (Fig. 5). The system is capable of performing multidimensional screening (mixing 5–10 solutions) and therefore explores more of the crystallization space than the conventional method of vapor diffusion, increasing the likelihood of obtaining crystals. Furthermore, the capillary containing protein crystals can be directly exposed to the synchrotron X-ray beam, eliminating the need to manually manipulate the crystal. These features also mean that it has the potential to serve as the basis for future high-throughput automated crystallization systems.

Membrane proteins represent the most persistent bottleneck for all preparatory procedures and analytical methods, because they are water soluble only in the presence of detergents, and are difficult to overproduce in the quantities required for structural studies. Membrane proteins, which constitute up to 30% of the protein repertoire of an organism, represent the targets for more than 50% of the drugs that are being currently used and tested. An adapted robotic system has recently been reported that enables high-throughput crystallization of membrane proteins using lipidic mesophases.

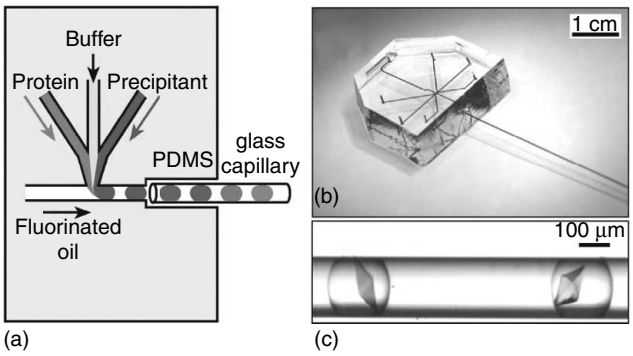

Fig. 5 (a) Schematic illustration of the droplet-based microfluidic system for protein crystallization. (b) Photograph of a polydimethylsiloxane (PDMS)/glass capillary composite microfluidic device. (c) A micrograph of thaumatin crystals grown in droplets, produced by the method outlined in panel (a), within a capillary. Taken from Zheng, B., Tice, J.D., Roach, L.S., Ismagilov, R.F. Chem., Int. Ed. Engl.* **43**, 2508–2511. Picture with permission from Dr. Rustem Ismagilov.

4.2 Data Collection

X-ray data collection has been revolutionized over the past decade, with the development of improved X-ray sources and detectors and the universal adoption of flash-freezing techniques that greatly reduce crystal radiation damage. New third-generation synchrotrons are now available across the world, which provide more intense and stable X-ray beams and, combined with new, faster, larger, and more sensitive X-ray detectors, allow higher-quality data to be collected much more rapidly, leading to a dramatic increase in the success rate of structure determination. Furthermore, specialized, highly collimated microfocus beamlines, such as ID13 at the ESRF (Grenoble, France; http://www.esrf.fr/exp_facilities/ID13/index.html) and the protein crystallography beamline at the Swiss Light Source (SLS), are specifically tailored to study biological crystals with small physical dimensions (microcrystals from 5 to 50 μm in size) or very large unit cell dimensions. Future developments in detector design, such as the MarResearch GmbH (Norderstedt, Germany) flat-panel detector, promise larger continuous active areas, higher spatial resolution, very low noise, and fast readout times (~1 s). High-throughput X-ray data collection has also led to the development of automated robotic sample changers that store and mount crystals sequentially while maintaining the samples at liquid-nitrogen temperatures (100 K). A novel system has recently been described, using a proprietary crystallization plate that facilitates the preliminary investigation of the diffraction properties of crystals *in situ* in the drop, by direct exposure to the X-ray beam. The BIOXHIT project (Biocrystallography (X) on a Highly Integrated Technology Platform for European Structural Genomics; http://www.bioxhit.org), comprising more than 20 research groups from all over Europe, aims to develop an integrated technology platform for synchrotron beamlines by promoting new approaches to crystallization, and fully automating diffraction data collection and structure determination.

Recent developments in technology have not been limited exclusively to synchrotron sources. The latest generation of high-intensity X-ray generators has revolutionized X-ray sources to such an extent that the latest ''in-house'' systems from Rigaku/MSC (e.g. the FR-E SuperBright; http://www.rigakumsc.com/) and Bruker AXS (http://www.bruker-axs.com) are comparable in intensity to first-generation synchrotron sources and, coupled with automated sample changers, make high-throughput crystallography possible in the laboratory. Furthermore, the development of the Compact Light Source (Lyncean Technologies, Inc., Palo Alto, CA, USA) promises to have a huge impact on protein structure determination, offering the possibility of a ''synchrotron beamline'' for home laboratory applications. This tunable, tabletop X-ray source combines an electron beam with a laser beam to generate an intense X-ray beam and, as a next-generation X-ray source, directly addresses the increasing demand for high-throughput protein crystallography.

4.3 Phasing

The central problem in X-ray crystallography is the determination of the protein phases. X-ray data collected from a crystal

consist of structure factor amplitudes, but there is no way of directly measuring the phase associated with each amplitude. Recent advances in macromolecular phasing have simplified and further automated this crucial stage of X-ray structure determination to such an extent that the eventual success of a project is usually assured, if well-diffracting crystals are available. The techniques of isomorphous replacement, anomalous scattering, molecular replacement, and single (SAD) and multiple (MAD) anomalous dispersion are commonly used to solve the phase problem. However, phase determination has been dramatically facilitated by the widespread adoption of SAD and MAD phasing techniques by the crystallographic community, primarily as a consequence of the availability of stable and tunable synchrotron sources. These allow the optimal exploitation of the anomalous effect as a source of phase information by delivering X-ray energies corresponding to absorption maxima of the anomalous scatterers, very often selenium introduced as selenomethionine through substitution of methionine. Additionally, heavy-atom labels (mercury, platinum, and others) may be bound to crystalline proteins by soaking to yield phase information by anomalous diffraction techniques.

Modern phasing techniques, such as fast halide soaks and sulfur-SAD, hold promise of simpler and faster protein structure determination than traditional methods. Fast halide soaks using bromide and iodide that diffuse rapidly into the crystal and display significant anomalous scattering signals can be used to quickly derivatize protein crystals. Heavy-atom reagents can also be incorporated into the crystal in a relatively short time if a concentration greater than 10 mM is used. These derivatives then display better isomorphism and diffraction qualities than those obtained after a standard, prolonged soak. The availability of stable synchrotron beamlines and improvements in data processing programs make it possible to collect extremely accurate diffraction data, and to determine structures using the very weak anomalous signals from atoms such as sulfur and phosphorus that are inherently present in macromolecules or nucleic acids; several novel structures have been determined by using sulfur-SAD phasing.

4.4 Automated Structure Determination

High-throughput crystallographic structure determination requires software that is automated and designed for minimum user intervention. There has been considerable development in the direct-method programs, SHELXD and SnB, which can automatically determine heavy-atom substructures from a very small signal. HKL2MAP connects several programs from the SHELX suite to guide the user from analyzing scaled diffraction data (SHELXC), through substructure solution (SHELXD) and phasing (SHELXE), to displaying an electron density map (Xfit). There are a number of other automated software systems, such as ACrS (automated crystallographic system) and PHENIX (Python-based hierarchical environment for integrated Xtallography) that are currently being developed to meet the requirements of high-throughput structure determination by combining multiple structure-determination software packages into one intuitive interface.

Finally, new algorithms for interpreting electron density maps and for automated model building, such as, SOLVE/RESOLVE, AUTOSHARP/

SHARP, and ARP/wARP, enable rapid construction of protein models without the need for significant manual intervention. At present, the success rates for these programs are dependent on the resolution of the diffraction data (typically, 2.5-Å resolution or higher is necessary for automatic chain fitting).

4.5 Molecular Replacement

When an approximate structural model of a protein under investigation is available, either from NMR, a homologous X-ray structure, or from homology modeling, initial phases can be obtained using molecular replacement where the homologous probe structure is fitted to the experimental data using three rotational and three translational parameters. The programs AMoRe and MolRep that are integrated into the CCP4i GUI simplify the problem of positioning a molecule in the asymmetric unit by running sequential rotational and translational searches. Advances in molecular replacement include the implementation of the maximum likelihood–based algorithms in BEAST, and the six-dimensional evolutionary search algorithm in EPMR. As the number of protein structures increases, it is anticipated that molecular replacement will become the standard method for structure determination, using a generalized search of all unique protein domains present in the PDB.

5 Structure-based Drug Design

Knowledge of the three-dimensional structure of proteins can play a key role in the development of small-molecule drugs, because being able to verify how lead compounds bind to their targets accelerates drug development and is more cost-effective. Notable drugs that have been successfully designed using protein three-dimensional structure information include the HIV protease inhibitors, Viracept™ (Agouron, USA and Eli Lilly, USA), and Agenerase™ (Vertex, USA; Kissei, Japan; Glaxo Wellcome, UK). However, it is usually necessary to screen a large number of protein–ligand complex structures in the iterative process of rational structure-based drug design. Hence, high-throughput protein X-ray crystallography offers an unprecedented opportunity for facilitating drug discovery. Recent advances in rapid binding-site analysis of *de novo* targets using virtual ligand (*in silico*) screening and small-molecule cocrystallization methodologies, in combination with the miniaturization and automation of structural biology, enable more rapid lead compound identification and faster optimization, providing a framework for direct integration into the drug discovery process. In the high-throughput structure determination of protein–ligand complexes, it is desirable to use tools that can locate, build, and refine the structure of the bound ligand with minimal human intervention. One such tool is X-LIGAND, part of the QUANTA software package (Accelrys, San Diego, CA, USA) that automatically searches for unoccupied regions of electron density in the structure of the protein–ligand complex in which it tries to fit the ligand.

6 Structure Determination by NMR

Solution-state NMR spectroscopy can serve as a technique complementary to X-ray crystallography in protein structure

analysis, particularly in the context of structural genomics initiatives, where many protein targets either do not crystallize or do not form crystals suitable for crystallographic studies (owing to small crystal size or poor diffraction quality). NMR measurements are performed in aqueous solution, obviating the need for growing crystals. This technique is applicable primarily to small proteins (<30 kDa) that are highly soluble (millimolar concentrations), and is particularly useful in the study of proteins that are partially unfolded in the absence of their appropriate binding partners. The additional technique of solid-state NMR is useful in providing structural information for some integral membrane proteins that may not be accessible using crystallographic methods. Furthermore, chemical shift perturbation studies can be used to validate proposed biochemical functions, to map ligand-binding epitopes, and to screen for small-molecule ligands in drug development.

High-throughput, NMR-based structure determination requires rapid and automated data acquisition and analysis methods. The major challenges in realizing this have been those of increasing instrumentation sensitivity (signal-to-noise ratio) and reducing the time required for data collection. These technical issues have been addressed by constructing new high-field magnets and by the recent introduction of cryogenic probes that operate at low temperatures (~25 K), permitting the investigation of proteins that have either low solubility or low yields from purification. Additionally, the application of TROSY (transverse relaxed optimized spectroscopy), a novel spectroscopic concept based on the selection of slowly relaxing NMR transitions, has provided significant sensitivity enhancements for large proteins.

The most time-consuming aspects of structure determination by NMR are the long data collection times necessary for independently sampling three or more indirect dimensions along with the time taken to interpret the correspondingly large number of spectra from $^{13}C/^{15}N$-isotope-labeled samples. Rapid resonance assignment is a prerequisite for high-throughput NMR structure determination; techniques such as reduced-dimensionality $^{13}C,^{15}N,^{1}H$-triple resonance NMR also avoid the sampling limited regime through the simultaneous frequency-labeling of two spin types in a single indirect dimension. Heteronuclear multidimensional data reduce complications arising from interspectral variations by maximizing the dimensionality of the spectra and decrease signal overlap of data sets sufficiently for the data to be analyzed automatically. Recent approaches to automated structure elucidation from NMR spectra include NOESY-Jigsaw, in which sparse and unassigned NMR data can be used to reasonably and accurately assess secondary structure and align it. The information thus retrieved is useful for quick structural assays for assessing folds before full structural determination and can therefore assist in fold prediction. Additionally, the program ATNOS (automated NOESY peak picking) enables automated peak picking and NOE signal identification in homonuclear 2D and heteronuclear 3D [^{1}H, ^{1}H]-NOESY spectra during *de novo* protein structure determination.

Keywords

Molecular Chaperones
Proteins that assist with the correct folding, assembly, or disassembly of other proteins *in vivo*, but are not considered components of the final functional structure.

Receptor
The receptor, usually in association with the translocation channel, recognizes the targeting sequence and directs the substrate to the translocation channel.

Signal or Targeting Sequence
A sequence or motif in a substrate for directing it to a particular location within the cell. The targeting sequence often is a conserved or consensus sequence at the N or C terminus of the protein.

Translocase or Translocon
A system catalyzing the transfer of a substrate across or into a (membrane) barrier.

Translocation Channel
A pore formed by proteins across the membrane that mediates the transport of a protein across or into a membrane.

From prokaryotic to eukaryotic cells, the movement of proteins across membranes as well as the integration into membranes is a fundamental process with shared mechanisms. Protein translocation pathways can be viewed as modular systems with basic components. Transported substrates contain targeting information that is decoded by receptors at docking sites. The substrate is then translocated across the membrane generally through a channel. A source of energy is often required and a translocation motor usually mediates translocation through the channel. In this chapter, we will summarize translocation systems in eukaryotic and prokaryotic systems, emphasizing common themes. Our understanding of protein translocation is continuing to grow with the addition of new components to existing systems and the identification of new translocation machines. The reader is encouraged to use this chapter as a starting point for more detailed excursions into scientific literature.

1 Overview of Compartmentalization

Membranes form important boundaries in cells to regulate selected exchange of molecules and ions between aqueous environments. The plasma membrane is a universal feature of all cell types and contains a wide range of transporters to mediate the exchange between the extracellular milieu and the cytoplasm. Eukaryotic cells also have developed compartmentalization

through membrane-bound organelles that specialize in various intracellular biochemical processes.

Experimental analysis using genetics and *in vitro* assays for protein targeting to eukaryotic organelles and the bacterial periplasmic membrane have revealed molecular details of the majority of protein translocation systems. The unifying principles of these systems were first proposed in the signal hypothesis two decades ago, although the components of the systems vary for each pathway. Prokaryotes first developed translocation systems for the translocation of proteins into the periplasmic space and for integration into membranes. The secretion (Sec) system mediates the translocation of proteins to the periplasmic space and has been evolutionarily conserved in the endoplasmic reticulum and chloroplast thylakoid. When the mitochondrion and chloroplast developed in the primitive eukaryotic cell, the progenitor's DNA became integrated into the host nucleus. As genes moved into the nucleus, novel translocation systems developed within the chloroplast and mitochondrion. The peroxisome also developed a translocation system seemingly independent of other organellar systems, which can translocate folded proteins.

2 Common Principles of Translocation

All translocons possess several essential features. A substrate possesses specific targeting information that directs it to the correct location. The targeting information is referred to as a *signal sequence* and is often found at the N terminus of a substrate. Molecular chaperones maintain the precursor in an import-competent state. Receptors are able to decode the information and direct the precursor to the oligomeric membrane complex, termed the *translocon*. Receptors are often bound to the membrane and may transiently associate with the translocation channel. The channel is an aqueous pore in the membrane that is gated, and mediates passage of the substrate across or into the membrane. The precursor generally passes through the channel in an unfolded state. Translocation requires an energetic input such as a membrane potential and/or nucleotide hydrolysis. A translocation motor is required to pull or push the precursor from the cis side (site of synthesis) to the trans side (destination site) of the membrane. The substrate is often processed and assembles into a multi-subunit complex.

Translocation systems can be defined as export or import systems depending upon the difference between the compartments on either side of the membrane. The export system is located in the bacterial plasma membrane, the endoplasmic reticulum, the chloroplast thylakoid membrane, and mitochondrial inner membrane. Proteins are exported from the cytosol into an extracytoplasmic compartment (i.e. the bacterial periplasm, the lumen of the endoplasmic reticulum and thylakoid, and the mitochondrial inner membrane). The import systems are located in the mitochondrial and chloroplast outer and inner membranes, and the peroxisome; this reference is based on the fact that the protein is translocated into a compartment that is functionally equivalent to the cytosol.

The translocons are remarkably flexible, able to accommodate hundreds of distinct proteins substrates while maintaining the permeability barrier of the membrane. The translocation channel must be gated to prevent solutes and ions from passing between compartments. The channel

must also recognize "stop-transfer" signals within integral membrane proteins and then gate laterally to allow diffusion of the transmembrane domains into the lipid bilayer. The channels therefore play an active role in translocation.

Two classes of translocons can be defined on the basis of the mechanism by which the substrate is translocated. The most common class, termed *signal-gated translocon* functions like the gated ion channel. The newly synthesized substrate moves through the channel in an unfolded conformation with the assistance of molecular chaperones. Because the precursor is maintained in an unfolded state, the single translocon can accommodate a wide range of substrates. The translocation reaction therefore is similar to that of ion or metabolite transport. In contrast, the second class is able to transport fully folded and/or oligomeric proteins of large dimensions while maintaining a membrane permeability barrier. This class is referred to as *signal-assembled* translocons and is present in peroxisomes, chloroplast thylakoids, and bacteria. Stable translocation channels have not been detected in these systems; thus, it has been proposed that the translocons are assembled in variable dimensions to accommodate the size of the translocated substrate.

3 Properties of Targeting Sequences

Proteins destined for transport into or across a membrane have a signal sequence, usually at the N terminus that is proteolytically cleaved on the trans side of the membrane. Depending upon the system, it is referred to as a *signal-*, *leader-*, *targeting-*, *transit-*, or *presequence*. Generally, export signal sequences are hydrophobic whereas import signal sequences are more hydrophilic. For the prokaryotic and endoplasmic reticulum export systems, the export sequences can generally be interchanged. However, import signal sequences cannot be interchanged between different organellar sequences; swapping the targeting sequence of a resident chloroplast protein to a mitochondrial targeting presequence alters trafficking from the chloroplast to the mitochondrion. Hence, import signals are important for directing a precursor to the correct organelle in the cytosol that contains several organelles including peroxisomes, mitochondria, and chloroplasts.

Signal sequences increase the specific interaction of a precursor with the appropriate transport machinery. The signal sequence may act as a folding inhibitor to maintain the transport competency of the precursor. As a precursor exits from the ribosome in *Escherichia coli*, the signal sequence inhibits folding, thus allowing the molecular chaperone SecB to bind to the precursor. SecB subsequently binds to SecA to deliver the precursor to the translocation channel. The signal sequence then interacts with components in the translocation channel. If the signal sequence is removed, export is severely inhibited, but export can be increased to normal rates by mutations in the translocation channel. Thus, SecB–SecA interactions are important for targeting, rather than the signal sequence. However, in most cases, the signal sequence acts as a true targeting signal because it is specifically recognized by cytosolic chaperones, targeting factors, or receptors.

For the bacterial and endoplasmic reticulum export systems, the targeting sequence is generally a short (~20 amino acids) sequence consisting of a hydrophobic core and short polar flanking regions

located at the N terminus. The targeting sequence is usually cleaved at the trans side of the membrane by a processing protease. If an export signal is not cleaved and possesses a hydrophobic core of 20 amino acids, the sequence can serve as a signal-anchor sequence to anchor the protein in the membrane, generating a transmembrane protein.

A protein with several membrane-spanning domains also can be generated by the sequential coordination of a signal sequence and a downstream hydrophobic stop-transfer sequence. The signal sequence serves as the initiator for translocation and the hydrophobic stop-transfer sequence arrests translocation, probably triggering a lateral opening of the translocation channel. The protein thus escapes from the translocation channel and becomes an integral membrane protein.

Mitochondria and chloroplasts contain an N-terminal bipartite targeting sequence for targeting and subsequent sorting within the organelle. Mitochondrial precursors are sorted to the matrix, inner membrane, and intermembrane space, whereas chloroplast precursors are directed to the thylakoid membrane and lumen, the stroma, and the inner envelope. The mitochondrial targeting sequence consists of an N-terminal amphipathic helix and is approximately 20 to 50 amino acids in length. One face is positively charged while the opposite face is rich in hydrophobic residues. Proteins destined for the intermembrane space contain a bipartite targeting sequence. Specifically, a hydrophobic ''stop-transfer'' domain to arrest translocation within the translocon is located after the targeting sequence. Import is coordinated by proteolytic cleavage to remove the N-terminal targeting domain in the matrix, followed by precursor arrest in the translocon, and subsequent proteolytic cleavage in the intermembrane space before release. In contrast, mitochondrial precursors targeted for the inner and outer membranes lack an N-terminal targeting presequence and instead, contain targeting information within the mature protein.

Chloroplast precursors contain an N-terminal transit sequence varying in length from 20 to 150 residues. Precursors destined for the thylakoids also contain a bipartite sequence in which the first N-terminal tract designates chloroplast targeting, followed by a thylakoid transfer domain. Transit sequences carry a net positive charge and are rich in hydroxylated amino acids serine and threonine. Interestingly, several transit sequences can be phosphorylated in the cytosol, which enhances import.

Peroxisomal proteins contain three different types of peroxisomal targeting sequences (PTS). For the matrix protein cohort, PTS1 and PTS2 have been characterized: PTS1 is a C-terminal three amino acid sequence (S/A/C)(K/R/H)(L/M) that has been easily identified as genome sequences have become available, whereas PTS2 is a nonapeptide sequence (R/K)(L/V/I)X_5(H/Q)(L/A) near the N terminus. For membrane proteins, a consensus sequence has not been identified, but sequences encompassing the transmembrane domains have been shown to be required for targeting so that both interact with a peroxisome chaperone and mediate insertion into the membrane.

Substrates of the twin-arginine translocation (Tat) system contain an N-terminal cleavable presequence with a twin-arginine motif containing a consensus SRR*X*FLK. The Tat-type signals are highly conserved throughout plant and bacterial kingdoms. In prokaryotes, the Tat and Sec systems

have to discriminate between the two types of precursors. Whereas Tat- and Sec-type targeting signals generally are similar, Tat-type signals are less hydrophobic than Sec-type signals and thus evade the Sec system.

In general, signal sequences for a given membrane transport system lack a strict consensus sequence. 25% of randomly generated peptides can function as signal sequences for various organelles, and roughly 5% of all sequences in the *E. coli* genome can direct a protein to the mitochondrion. Therefore, the secondary structure seems to be important for specific interactions with receptors.

4 Signal-gated Translocation Systems

4.1 The Sec System

The Sec system of bacteria (Fig. 1) and the endoplasmic reticulum (Fig. 2) share common properties. In addition, the chloroplast thylakoid also contains a Sec-related translocon. These translocons contain an oligomeric membrane–protein complex and associate with a translocation motor. The protein-conducting channel of this pathway is evolutionarily conserved in all kingdoms of life.

The bacterial system contains the SecYEG membrane complex that associates with the cytoplasmic ATPase, SecA. SecA functions as both a component of the cytosolic signal receptor complex and as the protein translocation motor. The SecYEG complex associates with the ribosome for cotranslational-membrane-protein insertion and with YidC, for assembly of membrane proteins. YidC has homologs in the chloroplast (Albino3) and mitochondria (Oxa1p).

4.1.1 The Prokaryotic Sec System

The bacterial Sec system utilizes cytosolic chaperones, a translocation channel, and an ATP-dependent translocation motor to push substrates into the periplasm (Fig. 1). The cytosolic SecB tetramer binds to the targeting sequence for precursors destined for export, thus functioning as a molecule chaperone. SecA is a multifunctional protein that acts as a chaperone and ATP-dependent translocation motor. In the cell, SecA is both membrane-associated and soluble. The soluble SecA also functions as a molecule chaperone; in the homodimeric state, SecA binds to the SecB–preprotein complex. When the

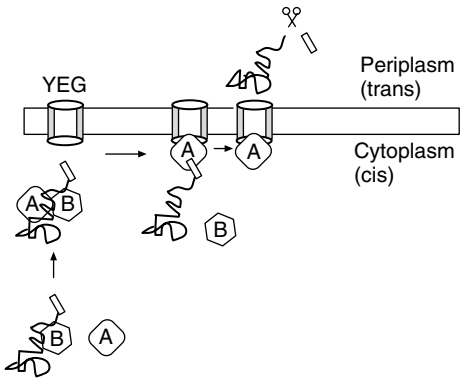

Fig. 1 The Sec translocation pathway for the export of bacterial proteins. Bacterial proteins are synthesized as precursors in the cytosol. SecB binds to the precursor and recruits SecA. The complex moves to the SecYEG translocon. SecB is released and SecA functions as a translocation motor to push the precursor through the SecYEG channel. SecA insertion is coupled with SecG inversion. Note: the channel is in a sealed conformation when not engaged or occupied by SecA.

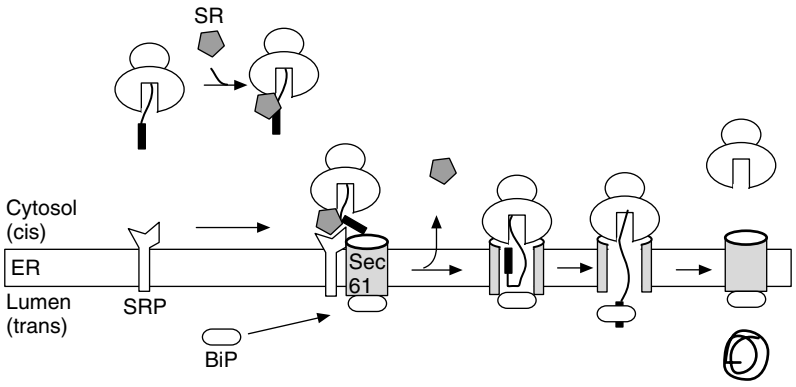

Fig. 2 The Sec cotranslational translocation pathway for the export of mammalian proteins via the endoplasmic reticulum. The soluble signal protein (SR) binds to the targeting signal as it emerges from the ribosome. The ribosome nascent chain complex is then escorted to the signal protein receptor (SRP) at the membrane. SR is released and the ribosome engages the Sec61 translocon, which causes opening of the translocon. The Hsp70 protein BiP gates the channel from the lumenal side and provides a seal to maintain membrane permeability. Translocation proceeds cotranslationally until protein synthesis terminates. The ribosome is released from the translocon and the translocon reverts to its closed state.

SecA–SecB–preprotein complex reaches the membrane, SecA associates with low affinity to negatively charged phospholipids and with high affinity to the translocation channel consisting of SecYEG. The preprotein is then transferred from SecB to SecA, and SecB is released by SecA upon the ATP-dependent initiation of translocation. The preprotein is then translocated through the SecYEG channel by multiple cycles of ATP binding and hydrolysis by SecA. Approximately 2 to 3 kDa segments are translocated per each ATP-dependent insertion reaction. The membrane potential is also required for translocation. SecA "pushing" from the cytosolic side compensates for the lack of a periplasmic energy source that could fuel molecular chaperones in the periplasmic space.

SecYEG forms the core of the protein-conducting channel and along with SecA is termed the *preprotein translocase*. SecY is the largest member of the protein-conducting channel and essential for viability and protein translocation. From experimental approaches and computer modeling, SecY contains 10 membrane-spanning domains with both N and C termini oriented to the cytosol. The fifth cytosolic loop is important for interactions with SecA. In contrast, SecE is a 14-kDa protein with three membrane-spanning domains in *E. coli*; the N terminus localizes to the cytosol while the C terminus faces the periplasm. Interestingly, other bacteria contain a SecE version that is homologous to only the third membrane-spanning domain, thus suggesting that this is an important region in SecE. SecG associates loosely with the protein-conducting channel and contains two membrane-spanning domains. SecG is an unusual protein because it undergoes an inversion in topology upon the membrane insertion of SecA. Although SecG is not essential for viability, it is required for efficient export at low temperatures.

What is the oligomeric state of the protein-conducting channel? The crystal structure from the archaeon *Methanococcus jannaschii* revealed a monomeric complex. However, the diameter of the channel is too narrow to accommodate SecA. Electron microscopy studies with purified SecYEG complex suggested a larger-sized complex of ~85 by ~65 Å with a pore of ~20 Å; the size and mass of these particles may reflect a dimeric or tetrameric form. From experimental studies including analytical ultracentrifugation and blue native gel analysis, it was revealed that the complex forms a dimer. The channel thus seems to have several different oligomeric assemblies. Further structural studies with the channel engaging SecA are required to provide a picture of the translocase in action.

4.1.2 The Mammalian Sec System

The mammalian system contains the SecYEG homologs Sec61α, Sec61β, and Sec61γ subunits, in addition to a unique subunit TRAM that is required for membrane protein integration (Fig. 2). The mammalian translocon forms an aqueous pore that spans the ER (endoplasmic reticulum) membrane, and Sec61α membrane-spanning domains line the channel similar to SecY. Ribosomes synthesizing membrane or secretory proteins are earmarked by a signal sequence at the N terminus of the nascent chain that binds to the signal recognition particle (SRP). SRP directs the ribosome nascent chain complex (RNC) to the signal receptor (SR) at the ER membrane. GTP-dependent interactions then elicit binding of the RNC directly to the translocon, followed by transfer of the nascent chain into the channel.

How is the protein translocated into the channel? The lumenal side of the pore is closed by the Hsp70 chaperone BiP. After RNC docking and elongation of the translocating chain, BiP is released from the pore, allowing passage of the chain into the ER lumen. The RNC then maintains an ion-tight seal on the cytoplasmic side. If a protein contains several membrane-spanning domains, BiP at the lumenal side and the RNC at the cytosolic side alternately gate the pore through a series of orchestrated changes, thus maintaining an ion-tight barrier between the lumen and cytoplasm during translocation of the protein. Specifically, as the nascent chain increases in length, BiP is released from the channel, while the ribosome maintains an ion-tight seal. Upon the detection of a membrane-spanning domain, the luminal end of the pore is closed by BiP, allowing the ribosome to then lift from the translocation channel. Translocated membrane proteins most likely are released laterally into the membrane via parting of the membrane-spanning domains in the Sec channel. The inner diameter of the pore changes dynamically from 9–15 Å in the ribosome-free closed state to 40–60 Å upon ribosome docking. The flexibility of the channel may be required to accommodate multiple membrane-spanning domains, which may leave the translocon in groups.

4.2 YidC is Involved in the Assembly of Membrane Proteins

YidC cooperates with the bacterial Sec system and operates independently to mediate translocation of integral membrane proteins. YidC is an integral membrane protein with six membrane-spanning domains and a large periplasmic domain. YidC interacts with the SecYEG translocon to facilitate integration of membrane proteins during translocation. YidC also acts

independently to mediate the insertion of subunits in the energy-transducing complexes such as the F_0 domain of the F_1F_0 ATPase. The chloroplast homolog albino3 is required for protein insertion into the thylakoid membrane and the mitochondrial homolog Oxa1p is required for protein insertion into the inner membrane.

4.3 Mitochondrial Protein Import Pathways

The mitochondrion contains two membranes that separate the mitochondrial matrix from the intermembrane space (Fig. 3). The inner membrane is essentially impermeable to ions because a membrane potential must be maintained for respiration. Most proteins are synthesized on cytosolic ribosomes and imported cotranslationally or posttranslationally into the mitochondrion. Proteins coded on the mitochondrial genome, however, are exported.

The mitochondrion contains a small genome and these proteins are exported to the inner membrane via Oxa1p. Oxa1p is homologous to YidC, but contains five membrane-spanning domains and a large C-terminal domain in the matrix. The ribosome docks on the C-terminal domain to facilitate translocation of newly synthesized hydrophobic membrane-spanning

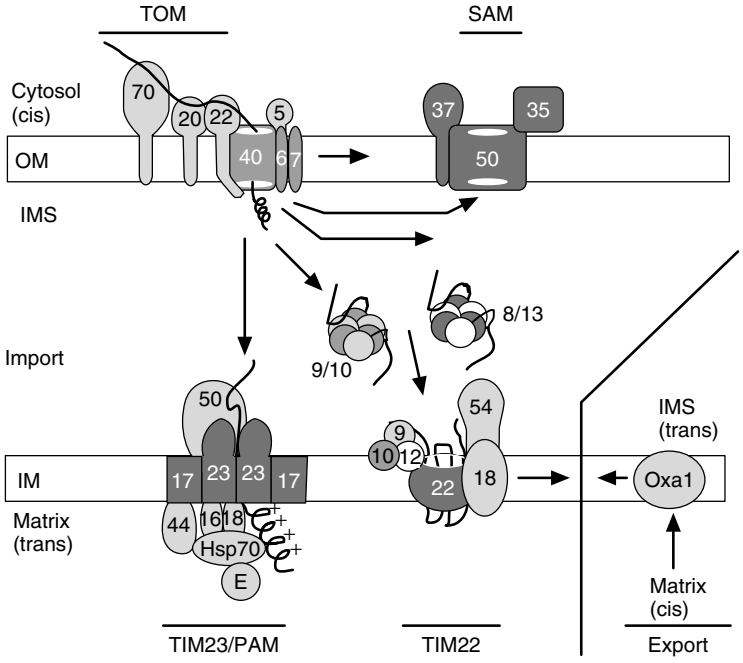

Fig. 3 Translocation pathways of the mitochondrion. Most proteins are imported from the cytosol and pass through the TOM complex. Single pass membranes are released from the TOM channel, whereas β-barrel proteins are sorted to the SAM complex for assembly. Proteins with a typical N-terminal targeting sequence are imported via the TIM23 translocon, whereas inner membrane proteins lacking an N-terminal targeting domain are imported via the TIM22 translocation system. Proteins coded by the mitochondrial genome are exported via Oxa1p.

domains into the membrane. Translocation depends upon the membrane potential. Structural studies suggest that Oxa1p functions as a tetramer, but whether it forms a translocation channel has not been established.

Most proteins are imported from the cytosol. The outer membrane contains the translocase of the outer membrane (TOM) complex through which all precursors are translocated. Cytosolic chaperones such as mitochondrial import stimulation factor and presequence binding factor have been identified in mammals, and the cytosolic chaperones Hsp70 and Hsp90 bind to the Tom70p receptor. Cotranslational import also has been implicated because mRNAs of prokaryotic origin have a signal in the 3′ untranslated region that targets them to the mitochondrion.

The TOM complex contains both, receptors and the translocation pore. The receptor Tom20p binds directly to the N-terminal presequence. In contrast, Tom70p mediates import of precursors that contain targeting information within the mature part of the protein. The precursors are then directed to the translocation pore formed by Tom40p. Small Tom proteins, Tom6p and Tom7p, are thought to gate the pore and allow proteins with one or two membrane-spanning domains to escape laterally into the lipid bilayer.

Proteins such as Tom40p and porin are β-barrel proteins and recently have been shown to be assembled by the sorting and assembly machinery (SAM) complex for outer membrane β-barrel proteins. The SAM complex consists of Sam50p, Sam35p, and Sam37p. Whereas Sam50p is also a β-barrel protein, Sam37p contains one membrane-spanning domain, and Sam35p is peripherally associated with Sam50p on the cytosolic side. The molecular mechanisms of this pathway remain to be elucidated, but preliminary studies suggest that the precursor is passed from the TOM complex via the intermembrane space to the SAM complex. Bacteria contain a homologous protein Omp85, which most likely assembles β-barrel proteins in the outer membrane and may be required for lipid biogenesis. Thus, the SAM pathway seems to be evolutionarily conserved.

For proteins with a typical N-terminal targeting presequence, they are imported from the TOM complex to the TIM23 complex. The TIM23 complex forms the membrane translocon and associates with the protein associated motor (PAM). The TIM23 complex contains the receptors Tim50p and the N-terminal domain of Tim23p, whereas Tim17p and the C-terminal domain of Tim23p form the translocation channel. A membrane potential is required to initiate translocation. The PAM then completes translocation in an ATP-dependent manner. The driving force is generated by the ATPase mHsp70, which is anchored to the membrane by Tim44p. The nucleotide exchange factor Mge1p promotes the reaction cycle of mHsp70, thereby allowing nucleotide release. Pam16p and Pam18p are associated J-proteins that stimulate the ATPase cycle. Upon translocation into the matrix, the targeting sequence may be proteolytically cleaved, and a battery of chaperones facilitates folding of proteins and assembly into functional protein complexes.

Proteins destined for the inner membrane utilize the TIM22 pathway. Precursors of this pathway include the mitochondrial carrier family such as the ADP/ATP carrier, and the phosphate carrier, as well as Tim17p, Tim22p, and Tim23p. In contrast to precursors with an N-terminal targeting presequence, these precursors contain targeting information within the mature part of the protein and cross the

TOM complex as a loop. The estimated size of the TOM translocon is ~20–26 Å, which can accommodate two unfolded polypeptide chains. As the hydrophobic precursors cross the TOM complex and enter the aqueous intermembrane space, the small Tim proteins escort the complexes to the TIM22 insertion complex at the inner membrane. The small Tim proteins are a family of five proteins in yeast. Tim8p partners with Tim13p and Tim9p partners with Tim10p to form 70-kDa complexes in the intermembrane space. The small Tim proteins bind to hydrophobic sequences in the inner membrane substrates and escort them to the insertion complex. The insertion complex contains the membrane proteins Tim22p, Tim54p, and Tim18p and associated Tim12p with a fraction of the Tim9p and Tim10p. Tim22p forms a twin-pore translocase that mediates import into the inner membrane. The mechanism of insertion into the membrane has not been elucidated, but a membrane potential is required. The auxiliary proteins Tim18p and Tim54p most likely play a role in complex assembly and stability.

4.4 Chloroplast Protein Import Pathways

The chloroplast organization is the most complex of all organelles. Proteins can be imported across three distinct membranes, the chloroplast outer and inner envelope membranes and the thylakoid membrane, and into three soluble subcompartments – the space between envelope membranes, the stroma, and the thylakoid lumen (Fig. 4). The translocase of the outer envelope (TOC) and the translocase of the inner envelope (TIC) coordinate the import of chloroplast proteins. Proteins are imported to the thylakoids by one of three different systems, the Sec pathway, the SRP pathway, and the Tat pathway. Additionally, proteins may insert spontaneously into the thylakoid membrane.

Most precursors are imported posttranslationally from the cytosol, except for proteins that are coded on the chloroplast genome. As the precursor emerges from the ribosome, molecular chaperones of the Hsp70 family prevent aggregation and maintain an unfolded import-competent state. The precursor may be phosphorylated by a cytosolic ATP-dependent protein kinase to ''fast-track'' import. Toc159 and Toc34 are GTPases and form the receptor system for directing the precursor to the membrane. Toc159 cycles between the cytosol and the TOC complex while Toc34 remains associated with the β-barrel channel Toc75. The GTP requirement has not been elucidated, but recent studies suggest a coordinated cycle in which GTP-dependent substrate recognition is coupled to GTP-driven translocation across the outer envelope.

The TOC complex has a molecular mass of approximately 550 kDa consisting of a stoichiometry of 4 Toc34 : 4 Toc75 : 1 Toc159. Toc75 is the most abundant outer envelope protein with a predicted topology of 16 transmembrane β-sheets. Toc75 forms a cation-selective ion channel when reconstituted into planar lipid bilayers. On the basis of electrophysiological measurements, the channel is an estimated 25 Å at the entrance and 15 to 17 Å in the middle, which could accommodate a single polypeptide chain. An accessory protein Toc64 might serve as a docking site for hydrophobic precursors bound to chaperone Hsp70.

The TIC complex is suggested to associate simultaneously with the TOC complex during translocation. In contrast

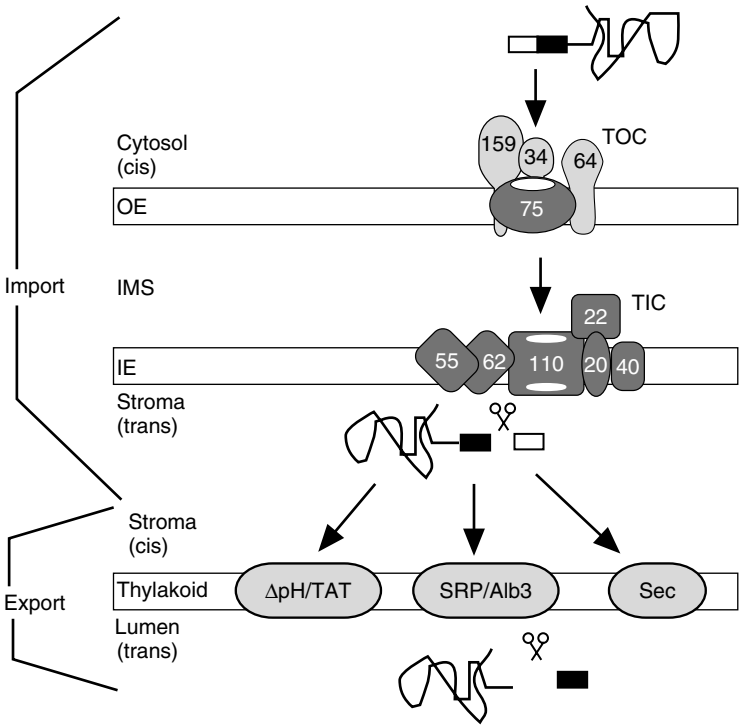

Fig. 4 Translocation pathways of the chloroplast. Precursors are imported from the cytosol and pass through the TOC complex and the TIC complex. In the stroma, the processing peptidase removes the transit sequence; for precursors destined for export to the thylakoid, cleavage of the transit sequences reveals the thylakoid targeting sequence for export via one of three systems.

to the GTP requirement at the TOC complex, ATP hydrolysis is required for translocation across the inner membrane, probably for stromal molecular chaperones that function as a translocation motor. The TIC complex contains several members including Tic110, Tic62, Tic55, Tic40, Tic22, and Tic20 and has a molecular weight of 250 kDa. Of these components, Tic110 is the best characterized and seems to bind to the TOC complex and stromal chaperones Hsp93 and chaperonin 60. Tic62 and Tic55 are redox components that may link the metabolic status of the chloroplast (based on the NAD(P)H:NAD(P) ratio) to the import capacity of the chloroplast. In *Arabidopsis thaliana*, many of the TIC and TOC components belong to multigene families, allowing complex regulation and reinforcing the importance of import in chloroplast biogenesis.

5 Signal-assembled Translocation Systems

5.1 Peroxisomal Import Pathways

Peroxisomes are single membrane-bound organelles that specialize in β-oxidation of fatty acids, hydrogen peroxide-based

respiration, and are a defense against oxidative stress. They are found in virtually every eukaryotic cell, with a typical size of 0.1–1 μ m in diameter. In plants, peroxisomes are specialized as glyoxysomes for the glyoxylate cycle, leaf peroxisomes involved in photorespiration pathways, and unspecialized peroxisomes. In mammals, peroxisomes are integral for fatty acid oxidation, and defects in its assembly lead to a class of inherited diseases referred to as *Zellweger's syndrome* or *peroxisome biogenesis disorders* (PBDs). Genetic and biochemical studies in yeast and complementation studies in cells derived from Zellweger's syndrome patients have proved instrumental in identifying many of the proteins involved in peroxisomal biogenesis, termed *peroxins* and coded by PEX genes. Approximately 25 to 30 peroxins have been identified and include both soluble and membrane proteins.

As with other organelles, events in biogenesis include import into the matrix and import of membrane proteins. The matrix protein pathway has been best characterized, but the current mechanistic understanding is not as refined as that of other organelles, because *in vitro* manipulations with peroxisomes are difficult: the organelles are difficult to purify and a robust import assay has not been developed. Biogenesis studies, however, have been advanced by groups working in several experimental systems. The striking differences of peroxisomal biogenesis in comparison with other organelles are that a typical translocation motor and channel have not been identified, and folded proteins can be imported. Additionally, peroxisomes do not possess a membrane potential.

5.1.1 Protein Import into the Matrix

Peroxisomal matrix proteins are synthesized on free ribosomes in the cytosol and imported posttranslationally into peroxisomes, emphasized with PTS1 precursors that have the targeting information at the C terminus. From experimental systems, the simple PTS1 can target a nonresident protein such as green fluorescent protein to the peroxisomal matrix, verifying that the PTS1 sequence is necessary and sufficient for targeting to peroxisomes. The import of matrix proteins depends on cytosolic receptors Pex5p and Pex7p, for PTS1 and PTS2 precursors, respectively (Fig. 5). Pex5p consists of two domains; the C-terminal half contains a high-affinity PTS1-binding site consisting of seven tetratricopeptide repeats (TPR), whereas the N-terminal half mediates peroxisomal targeting and protein–protein interactions at the organelle. Pex7p contains WD-40 motifs and works in conjunction with accessory proteins to guide the precursor to the peroxisome. The cytosolic chaperones thus bind to their cargo and the complexes dock independently at the peroxisome surface.

The docking platform consists of Pex13p, Pex14p, and Pex17p, of which Pex13p and Pex14p are integral peroxisomal membrane proteins (PMP). Both Pex5p and Pex7p converge to this dock, implicating a single translocon for both types of cargo. Peripherally associated Pex17p forms a tight core with PMP Pex14p. Pex13p exposes the N and C termini to the cytosol and recognizes both Pex5p and Pex7p. Pex7p binds to the N terminus, and Pex5p and Pex14p binds to the C terminus, which contains an Src-homology-3 (SH3) domain.

A second group of membrane proteins, Pex2p, Pex10p, and Pex12p (the

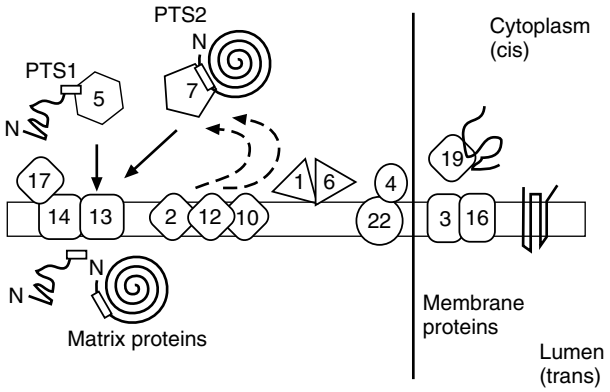

Fig. 5 Translocation pathways of the peroxisome. Pex5p chaperones PTS1 precursors and Pex7p chaperones PTS2 precursors to the docking complex consisting of Pex13p, Pex14p, and Pex17p. The precursor is translocated into the thylakoid lumen and Pex5p and Pex7p are recycled to the cytosol. Peroxisomal membrane proteins are chaperoned to the membrane by Pex19p and associate with Pex3p and Pex16p for insertion into the membrane. Peroxisome translocation mechanisms are not well understood but folded, proteins can be translocated.

RING-finger peroxins), function downstream from the receptor complexes. All three components contain cytoplasmic zinc RING domains, and Pex10p and Pex12p bind to Pex5p. How does Pex5p deliver cargo to the peroxisomal matrix? The mechanism by which Pex5p releases cargo has been under debate because Pex5p has been localized to the cytoplasm, peroxisomal membrane, and peroxisomal matrix. It has been suggested that Pex5p shuttles between the cytoplasm and peroxisomal matrix. In the ''extended-shuttle'' mechanism, Pex5p undergoes multiple cycles of translocation in and out of the matrix, whereas in the ''simple shuttle'' mechanism, Pex5p stays at the surface of the membrane and releases the cargo. The consensus is that Pex5p traverses the mammalian peroxisomal membrane through multiple rounds of entry into the matrix and export to the cytosol. Further evidence that Pex5p at least traverses the membrane is confirmed by an interaction between Pex5p and Pex8p, the only known peroxin localized to the trans side of the membrane in *Saccharomycescerevisiae*.

Additional peroxins, Pex4p, Pex22p, Pex1p, and Pex6p, are required to unload the cargo and return the receptor to the cytoplasm. Pex22p is a PMP that serves as a membrane anchor for cytosolic Pex4p, an E2-type ubiquitin conjugating enzyme. The RING-finger domains of Pex10p may interact with Pex4p to link the docking complex. ATP hydrolysis is required for import of matrix proteins, providing the potential for a nucleotide-hydrolysis–driven import cycle. Pex1p and Pex6p are two membrane-associated ATPases of the AAA family (ATPases Associated with diverse cellular Activities). Genetic studies place the requirement for Pex1p and Pex6p between receptor docking/translocation and Pex4p/Pex22p,

suggesting that Pex1p and Pex6p are required for unloading the cargo and recycling the receptor.

5.1.2 Protein Import into the Membrane

Matrix protein and PMP import seem to be independent. In contrast to matrix protein import, PMP import does not require ATP hydrolysis, and mutations in genes that abrogate matrix import usually do not affect membrane import. Furthermore, a translocation intermediate that blocked the binding of matrix proteins to isolated glyoxysomes did not affect PMP import.

Thus, of most *pex* mutants in which matrix import is abolished, PMPs are still inserted into peroxisome remnants or ''ghosts'' because they lack matrix proteins.

However, in cells that are deficient in the PMPs Pex3p, Pex16p, and Pex19p, peroxisome ghosts are not detectable, suggesting that this cohort defines the essential components for PMP import and sorting. Supporting this, mutant cells are seen to lack *pex3* or *pex19* and have unstable PMPs. And these three peroxins interact *in vitro* and *in vivo*.

Like peroxisomal matrix protein import, PMP import seems to share common features (Fig. 5). Pex19p is predominantly cytosolic, but can be found associated with the peroxisomal membrane, possibly via farnesylation at the C terminus. Pex19p thus acts as a chaperone to prevent PMP degradation and to guide PMPs in the cytosol to the peroxisome. As expected, Pex19p binds to several PMPs. In addition to its chaperone role, Pex19p subsequently acts as an import receptor, binding to the docking protein Pex3p. Pex3p thus acts as a docking protein, and as expected, Pex3p inserts independently of Pex19p. A specific role for Pex16p in PMP targeting is not known, but Pex16p may function at an early stage of peroxisomal membrane assembly upstream of Pex3p and Pex19p. Thus, peroxisomal import pathways share the common feature of a cytosolic chaperone, which targets both membrane and matrix proteins to docking sites on the membrane.

5.2 The Tat/ΔpH Pathway of Bacteria and Thylakoids

The Tat system (also referred to as the ΔpH pathway) is conserved in bacteria and chloroplast thylakoids (Fig. 6). The pathway was first characterized in plant chloroplasts in the early 1990s when biochemical studies showed that the pH gradient, rather than a nucleotide hydrolysis,

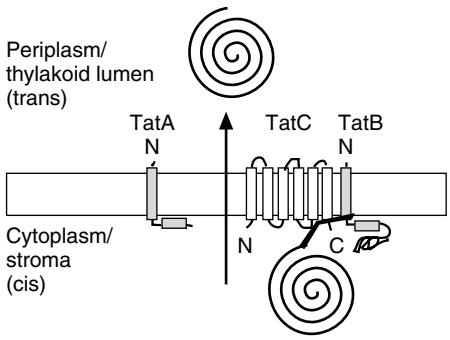

Fig. 6 The Tat/ΔpH translocation pathway for folded proteins. The Tat pathway of the thylakoid lumen and bacteria share common features. TatB and TatC assemble into a complex that binds to the Tat signal sequence. TatA is then recruited and the folded protein is translocated across the membrane in a membrane potential/ΔpH-dependent manner. A nucleotide requirement and chaperones on the cis and trans sides of the membrane have not been identified.

was required for the import of a subset of thylakoid lumenal proteins. The observation of the pathway in prokaryotes led to rapid identification of its important components. The Tat pathway mediates the translocation of large, folded proteins, such as proteins with a range of redox cofactors, including FeS, NiFe, and molybdopterin centers, across the tightly sealed membrane. In some cases, the oligomeric substrates employ a ''hitchhiker'' mechanism in which only one or a subset of subunits contain targeting signals. In most prokaryotes, the Sec system is the main route for export, but in the halophilic archaeon Halibacterium sp NRC-1, the majority of secretory proteins including traditional Sec-dependent substrates, use the Tat system. The rationale for this adaptation is that the haloarchea has a very high cytoplasmic salt concentration (4–5 M) and newly synthesized proteins must fold quickly to prevent aggregation; hence, the Tat system is required for export of these folded cytoplasmic proteins.

How does the Tat system translocate a folded protein across an energy-transducing membrane? With chloroplast thylakoid import studies, a precursor was constructed with a Tat signal fused to bovine pancreatic trypsin inhibitor (BPTI), which was internally cross-linked to prevent unfolding. This construct imported into isolated chloroplasts and targeted to the thylakoid lumen by the Tat pathway. In a second study, a larger translocation substrate was generated using the reporter dihydrofolate reductase (DHFR), which when folded binds to the folate analog methotrexate (MTX) with very high affinity. This translocation intermediate normally arrests in the mitochondrial TOM or bacterial Sec system because it cannot be unfolded, thus confirming that most translocons must completely unfold proteins prior to translocation. However, the folded DHFR-MTX construct was imported efficiently into the thylakoid lumen, and folding was confirmed because the DHFR–MTX complex was protease resistant. In bacterial systems, GFP (green fluorescent protein) fusions also were used to confirm that folded proteins were exported via the Tat system. Specifically, GFP that is engineered for export via the Sec system does not fold properly in the periplasm and does not fluoresce. In contrast, Tat-targeted GFP exported to the periplasm was folded and detected as a fluorescent halo on the cell periphery, confirming efficient translocation of a folded protein.

Because the Tat pathway is organized in one operon in *E. coli*, characterization of the translocation components was facilitated by identification of the proteins within the operon. The *E. coli* system has three Tat proteins (the tatABC operon) and plants have three (Tha4, Hcf106, and cpTatC for tatA, B, and C respectively) homologs. All Tat proteins are located in the membrane. TatA and TatB both contain one transmembrane domain (N terminus facing the periplasm), whereas TatC contains six membrane-spanning domains (N and C termini exposed to the cytoplasm). The TatABC complex is approximately 500 to 600 kDa in size and consists of approximately a 1 : 11 ratio for the individual components, although TatA is present in higher amounts or in a separate complex. From single particle electron microscope images, the TatABC complex has dimensions of 10×13 nm. TatB/Hcf106 and TatC form a stable membrane complex that binds the Tat signal. This then triggers the recruitment of TatA to form the functional translocation system, which requires a membrane potential. For the actual

translocation of the substrate, additional factors on the cis and trans side of the membrane seemingly are not required. The current available evidence suggests that the force may be applied within the membrane domain or by structural changes within the Tat translocon itself. After translocation, dissociation of the Tat translocon has been observed, which is consistent with the reversible assembly of the translocon.

Whereas the specific mechanism of transport remains to be elucidated, the transport of large folded proteins is very efficient, but costly. Careful measurements of the prevailing ΔpH during translocation of thylakoid proteins has shown that translocation requires 30 000 protons per protein transported. Moreover, two differently sized substrates required differing levels of ΔpH for translocation, suggesting that the Tat system adapts energetically to the size and/or shape of the substrate. Indeed, future mechanistic studies should provide new ideas about how large folded proteins can be exported across an energy-transducing membrane.

6 Conclusions

Significant progress has been made toward understanding the mechanism of protein translocation across membranes. Yet, there are major questions to be addressed. The events that initiate the translocation reaction have not been deciphered in all translocation systems. The mechanism by which the channel can accommodate precursors of varying sizes, particularly for the signal-assembled translocon, remains a mystery. Moreover, how defects in the translocation systems result in the diseased state in plants and animals are beginning to be elucidated. Eventually, a greater understanding of the mechanisms of translocation will provide information about the broader question of how membrane components assemble.

Keywords

Electrospray Ionization (ESI)
Electrospray is the process of ionization by which fractionated peptides are sprayed in solution through a charged needle toward the mass analyzer.

Isotope-coded Affinity Tag (ICAT)
Isotope-coded affinity tags are reagents used for quantifying the differential expression of peptides by mass spectrometry. ICAT tags contain three key components: a reactive group for labeling peptides (e.g. iodo-group for labeling cysteines), a group for affinity separation (e.g. biotin), and a spacer. The spacer can be derivatized with different isotopes (e.g. hydrogen or deuterium) to discriminate protein expression of peptides from different samples. The ratios of the heavy and light isotopes measured by the mass spectrometer may then be correlated with the relative abundance of the peptide in the two samples.

Liquid Chromatography–Mass Spectrometry (LC-MS)
Liquid chromatography–mass spectrometry is the separation of complex mixtures of peptides or protein samples by liquid chromatography followed by mass spectrometric analysis. Reverse phase liquid chromatography is usually performed on peptides as this utilizes volatile solvents compatible with mass spectrometry.

Mass Spectrometry
Mass spectrometry is a biophysical methodology used to measure the mass-to-charge ratio of proteins or peptides. The method involves the generation of ions in a vacuum from a solid peptide or a peptide in solution, followed by their detection and mass analysis. Mass spectrometry instruments therefore contain a source of ionization to convert the analyte into ions within the gas phase and a mass analyzer for the detection of the ions. Various methods exist for the generation of ions, including electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). Methods for detecting and analyzing the ions include time of flight (TOF) analyzers, quadrupole electric fields and ion traps.

Matrix-assisted Laser Desorption Ionization (MALDI)
In matrix-assisted laser desorption ionization, ions are formed via the laser excitation of samples embedded in a chromophore matrix. Laser energy excites the chromophore and the energy is transferred to the analyte, which ionizes and enters the gas phase. The mass-to-charge ratios of these ions are usually measured by the ''time of flight''

(TOF) from their release until detection. The time of flight can thus be converted into accurate molecular weight values.

Posttranslational Modifications
This is the process by which proteins are structurally modified following translation by the ribosomes, which may lead to altered function or activity. These include deamidation, proteolytic cleavage such as C-terminal truncation, phosphorylation, and glycosylation.

Protein Arrays
These consist in the microarray-based analysis of proteins either in a planar (chip) or suspension format, to qualitatively or quantitatively characterize protein expression or function.

Proteome
The proteome is the complete collection of proteins expressed in a given cell or tissue under a given set of conditions (normal, disease, treated or untreated with stimulants or compounds).

RNA Interference (RNAi)
RNAi (RNA interference) refers to the introduction of homologous double-stranded RNA (dsRNA) to specifically target and thereby silence the expression of one or more genes in a variety of organisms and cell types (e.g. worms, fruit flies, mammalian cells), resulting in null or hypomorphic phenotypes.

Surface-enhanced Laser Desorption Ionization (SELDI™)
In surface-enhanced laser desorption ionization, the analyte(s) are applied in solution to a protein-binding surface or ''chip'' followed by treatment with a MALDI matrix. The essential element of SELDI is the chemically modified nature of the surface, which facilitates selective adsorption prior to analysis. Laser desorption will release the bound proteins as ions (analogous to MALDI). The ion spectrum can be analyzed and specific patterns compared across different sample groups.

Tandem MS (MS/MS)
Ions detected by mass spectrometry can be selected for further fragmentation into ion products. The fragmented ion spectra contain more detailed information, which can be used to derive *de novo* sequence information about the peptide.

Transcriptomics
Transcriptomics is the study of the transcriptome, the collection of RNAs expressed in a given cell or tissue under given conditions (normal, disease, treated or untreated with stimulants or compounds). The commonly used method to study the transcriptome is microarray, also called *gene chip*, technology that allows the analysis of gene expression to be determined for all genes in a genome.

Two-dimensional Gel Electrophoresis (2-DE)
Two-dimensional gel electrophoresis (2-DE) is the separation of proteins in a polyacrylamide gel matrix, based on two properties. Separation in the first dimension is determined by the isoelectric point of the proteins being analyzed, while the second dimension separates them according to their apparent molecular weight.

Yeast Two-hybrid (Y2H)
This method was developed for the identification of protein–protein interactions using yeast as a host organism. A gene sequence encoding either a protein or part of a protein of interest is fused to the DNA-binding domain of a known, site-specific transcription factor (''bait''), while a single target gene sequence or library of such gene sequences (which may be prepared from a range of tissues etc.) for a potentially interacting protein(s) is fused to the transactivation domain of the same transcription factor (''prey''). Association between these two fusion proteins in yeast facilitates the reconstitution of the DNA binding and transactivation domains as a functional transcription factor, resulting in activation of a selected reporter gene placed under control of a promoter regulated by the transcription factor. Expression of the reporter can be monitored by a variety of methods.

The past century has witnessed many impressive advances in molecular biology and medical research, leading to both increased understanding and improvements in the treatment of many diseases. A notable example of this is the impact that the discovery of antibiotics had in treating bacterial infections. One of the most remarkable achievements was the discovery of the structure of DNA by Crick & Watson, an event that subsequently led some 50 years later to the completion of the sequencing of the entire human genome. This milestone has created a wealth of information and novel avenues for a more focused and comprehensive search and understanding of the biochemical, regulatory and structural function of the proteins encoded by the genome – a phase of biological exploration now referred to as the *postgenome era*.

In the postgenome era, there is significant work ongoing not only on the genetic aspects of biology but also the molecular processes guiding gene expression and function at all levels. These include RNA and protein synthesis and their regulation, protein modifications, protein–protein interactions (pathways), and metabolite formation. This review will focus on Proteomics, the study of global gene expression at the protein level. We will describe both currently used and emerging technologies for exploring universal protein expression, including protein fractionation, analysis, and quantification of complex protein solutions. In particular, this review will focus on characterizing the roles of proteins in pharmaceutical research and development, including exploring applications in determining the functional role of proteins and their relevance in human disease, as surrogate biomarkers for predicting/diagnosing disease, disease progression, and for determining compound efficacy and toxicity. Finally, we will assess what are the future prospects of utilizing protein research to reach a better knowledge of gene/protein function in normal and disease biology as well as clinical applications.

1 Definitions

1.1 Proteomics

The rapidly evolving nature of protein analysis has resulted in an ever-expanding definition of the term ''proteomics.'' While it is accepted that proteomics concerns the study and characterization of all proteins, including their synthesis, modifications, function and interactions, the evolution of separation and identification techniques has generated more specific definitions of proteomic activities such as expression proteomics and interaction proteomics. In addition, specific applications have emerged including clinical proteomics and toxicoproteomics.

1.2 Expression Proteomics

Expression proteomics is defined as the global separation, quantification and identification of expressed proteins in organisms, tissues, or cells under normal or other conditions such as disease or following compound treatment. Initially, this area was centered on 2-DE, but the recent development of nongel-based methodologies such as LC-MS and protein arrays have also started to show promise in this area.

1.3 Interaction Proteomics

Interaction proteomics is the study of specific protein–protein or protein–compound interactions and, more generally, the study of the role of protein complexes within biological pathways. Different methodologies such as the yeast two-hybrid system, phage display, protein arrays, and affinity purification of complexes followed by mass spectrometric analysis have been successfully applied to interaction proteomics studies.

1.4 Clinical Proteomics and Toxicoproteomics

Two particularly exciting emerging fields of expression proteomic research relating to clinical applications are clinical proteomics and toxicoproteomics. Clinical proteomics consists in the identification of biomarkers for disease detection or progression, or even regression after medical therapeutic treatment, whereas toxicoproteomics is the elucidation of potentially toxic or pathological effects of chemical agents or environmental factors.

2 Technologies

2.1 2D Gel Electrophoresis (2-DE)

Since the inception of proteomics as a discipline, 2-DE has been the technique most widely used for protein separation and analysis. This is still the case today, with relatively little changes from its original process developed about 30 years ago by O'Farrell, although a number of complementary approaches are being developed. In 2-DE, the separated proteins are visualized by either pre- or postelectrophoretic stains, class-specific stains (e.g. phosphorylation), or by autoradiography for radiolabeled proteins. Typically, between 2000 and 3000 proteins can be resolved in a standard 2-DE gel (Fig. 1). The technique is robust, quantitative, and relatively simple to implement with reasonably high throughput.

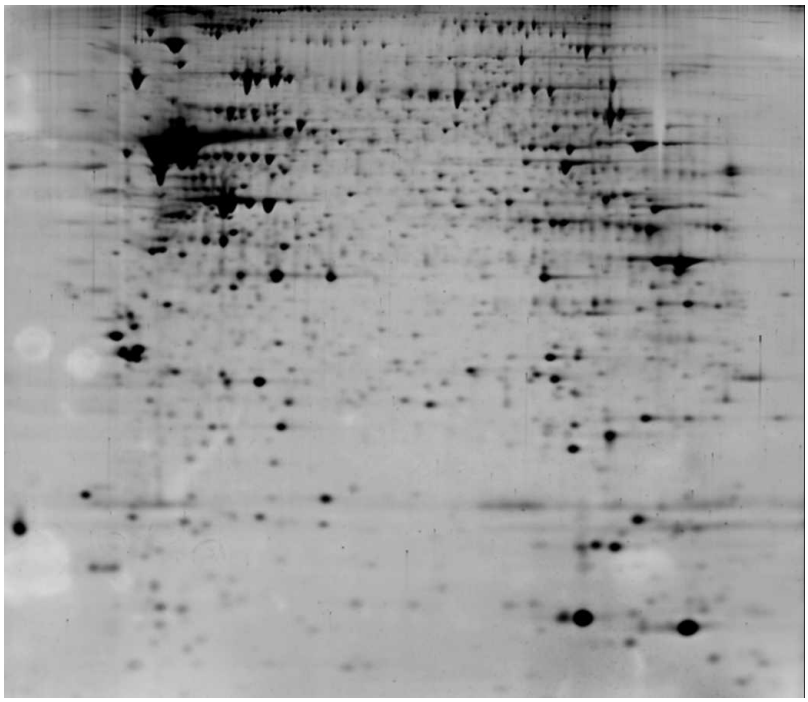

Fig. 1 Two-dimensional polyacrylamide gel separation of proteins from a complex mixture, illustrating separation by isoelectric point in the first (horizontal) dimension and separation by size in the second (vertical) dimension.

Major improvements have enabled greatly increased coverage, reproducibility, and accuracy. These include advances in sample preparation, electrophoresis methodology, as well as sensitivity and quantification of staining. Furthermore, scanning hardware has dramatically improved as have the available algorithms for image analysis and data mining.

Although unparalleled in its resolving power and flexibility, the performance of 2-DE is ultimately finite. Proteins are commonly detected in biological tissues over a dynamic range of $>10^6$. In plasma, the dynamic range has been reported to be on the order of 10^{12}. Because of this huge expression range, high abundance proteins may ultimately mask the visibility and detection of low abundance ones.

There are no ''amplification'' techniques for proteins analogous to the polymerase chain reaction (PCR) used for transcript identification and quantification. As proteomics is a substrate-limited technique, it is crucial that sufficient sample is available as starting material for analysis. Prefractionation is increasingly becoming a prerequisite for broad proteome coverage. In addition, the technology is biased against proteins with extremes of size, charge, and hydrophobicity. In order to address these ''problematic'' proteins, a number of novel approaches are being developed. These include multicompartment electrophoresis for enrichment of proteins on the basis of native charge and subcellular fractionation, in particular, isolation of organelle components such as mitochondria and

nuclei. As a consequence, initiatives to define the subcellular complement of the nuclear and mitochondrial proteomes are being actively pursued. This type of more focused proteomic analysis has increased sensitivity and has enabled analysis of the nuclear envelope and even the nuclear pore complex. Techniques have also been developed to preenrich proteins by functional class (e.g. proteases) and to specifically remove high abundance proteins. Such approaches include removal of albumin and other highly abundant proteins from plasma and serum prior to clinical proteomic studies.

The original carrier ampholyte-generated pH gradients of the 1970s have now been replaced with immobilized pH gradients (IPG) for isoelectric focusing (IEF). These matrices provide stable and reproducible gradient separations and are available commercially in broad pH range gels (e.g. pH 3–11) and extremely narrow pH range gels (e.g. pH 5–6), enabling extremely high resolution to be attained.

The performance of the second dimension has also been enhanced with the introduction of better instrumentation. In particular, reproducibility and throughput has been improved, while the introduction of the stable gradient gels has increased the resolution and flexibility of the technique. In conjunction with other advances, 2-DE is now capable of producing quantitative and reproducible data at a throughput compatible with biologically significant sample numbers.

The introduction of highly sensitive fluorescent dyes is greatly improving protein detection in gels. Fluorescent stains such as SYPRO Ruby have a better dynamic range, are more quantitative and are more compatible with mass spectrometry than previous stains (e.g. silver stains). A direct consequence of improvements to the performance of the technology is the separation of isoforms of proteins differing by single deamidation or phosphorylation modifications. Subsequently, stains specific for phosphorylation and glycosylation were developed and used successfully for proteins separated by 2-DE. An additional advance is the use of differential gel electrophoresis, incorporating prelabeling protein samples with fluorescent dyes and the ability to run two or even three samples on the same gel for comparative analysis.

Overall, 2-DE remains one of the most reliable and widely used techniques for proteome analysis. This is particularly true for sample profiling and for the analysis of differential protein expression in differing disease states or after treatment of cells or tissues with biologically or medically relevant agents or compounds. The continuous development of new techniques and instrumentation means that the limitations of the technique are constantly being reappraised and 2-DE will remain a very valuable approach for the foreseeable future.

2.2 Mass Spectrometry

One of the fundamental challenges of proteomics work is the requirement for sequence identification of proteins from a given sample following separation. Until a few years ago, the classical protein identification procedure was performed through N-terminal amino acid sequencing, known as *Edman degradation*. The development of mass spectrometry has essentially replaced Edman's method by virtue of providing more sensitive detection and higher sample throughput. These features, coupled with the rapid expansion of genomic databases, have provided

a revolutionary approach to protein detection and identification. The key steps describing the use of mass spectrometry to identify proteins from polyacrylamide gels are shown in Fig. 2.

In general, mass spectrometry is performed on tryptic peptides rather than intact proteins as their extraction from the microreticular polyacrylamide matrix of 2-DE is more facile. In addition, peptides are more readily amenable to ionization and analysis. This is not trivial as it necessitates a method for efficiently digesting proteins within the gel and recovering the resulting peptides. The proteases routinely employed, such as trypsin, are presented to the protein substrates, which are present within the gel at concentrations significantly below the Michaelis constant of the enzyme. Nevertheless, methods have been optimized, which enable efficient fragmentation of the proteins *in situ*.

The main principle of mass spectrometry is the accurate measurement of the masses of the peptide ions and derived peptide fragment ions from the analyses. The first requirement for analyte characterization is the generation of ions in the gas phase. In particular, the so-called ''soft ionization'' methods of matrix-assisted laser desorption ionization (MALDI) and

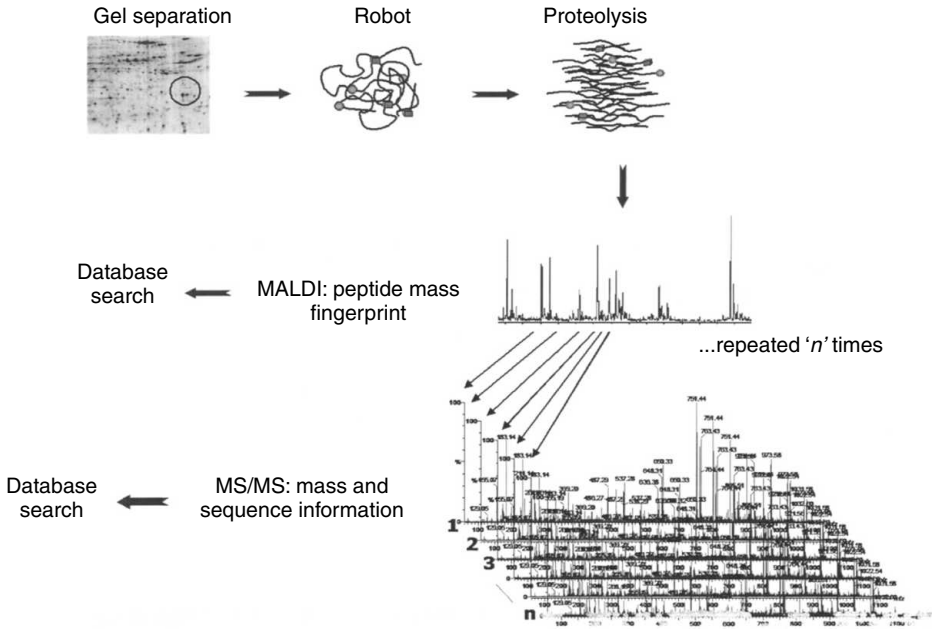

Fig. 2 Qualitative identification of proteins from gels by mass spectrometry. A spot of interest is excised from the gel and digested to peptides by trypsin. Two main methods exist for identifying a protein from the peptides generated. Firstly, the mass of the peptides may be determined by mass fingerprinting and compared to genomic data present in bioinformatics databases. Alternatively, individual peptide ions can be sequentially selected for fragmentation, which generates *de novo* sequence information. A combination of the sequence information and the peptide mass can be used to accurately assign a protein identity by comparison to the genomic database.

electrospray ionization (ESI) have made a dramatic impact on proteomics.

In MALDI, a laser pulse is applied to the sample that is embedded in a matrix (chromophore), which absorbs light at a specific wavelength. The energy in the chromophore is passed to the analyte peptide, which ionizes. The ions created are guided by a strong electrical field into the mass analyzer. MALDI is a particularly "soft" ionization technique resulting in singly charged peptide ions where the mass-to-charge (m/z) ratio reflects the mass of the peptide. This technique is most often used to measure the masses of peptides derived from enzymatic digestion of a protein. This is often referred to as the "*fingerprint*" of the protein and may be sufficient to identify the protein against a genomic database.

In ESI, ions are formed by electrospraying a peptide solution into the mass spectrometer via a small needle in the presence of a strong electrical field, creating small ionized droplets. The solvent in the droplets is eliminated by applying a counter current flow of gas or heat. Once the ions have entered the mass spectrometer, the mass analyzer separates and measures the ions on the basis of their mass-to-charge ratio (m/z) using electric or magnetic fields with subsequent registration by the detector. In ESI, a series of ions of different charges ($z = 1$, $z = 2$, $z = 3$, etc.) may be formed and these have to be deconvoluted to determine the mass of the parent peptide. This technique provides higher energy ions suitable for fragmentation and *de novo* sequencing. Relative abundance of the peptide will be reflected by the ion current in the analyzer. The ion current intensity will also be a reflection of the propensity of a particular peptide to ionize, which is in turn predicated on the amino acid composition. These confounding influences make absolute quantification without the use of internal standards complex.

In its simplest mode, the mass spectrometer defines the mass of the parent peptide ion. Peptides can then be selected manually or automatically within the mass spectrometer and further fragmented by collision with an inert gas. Peptides undergoing this process (tandem MS or MS/MS) tend to fragment at the amide bond, leading to a mass spectral ladder, whose steps reflect the mass differences between the parent ions sequentially depleted of the terminal amino acid residue (Fig. 2). It is therefore possible to derive *de novo* sequence information and, by reference to genomic databases, unequivocally identify a protein from a single peptide.

In recent years, different variants of mass spectrometry have emerged, encompassing novel approaches for trapping and selecting ions (ion traps, quadrupoles) as well as new mass analyzers such as time of flight (TOF) and Fourier transform ion cyclotron resonance (FT or FTICR-MS). As with the more classical approaches, performance is dependent upon the key parameters of mass accuracy, resolution, and sensitivity.

Biological samples are often extremely complex, and gel-derived digests often contain reagents incompatible with mass spectrometers. To circumvent these issues, separation technologies such as chromatography have been coupled to mass spectrometry. As with 2-DE, methods of fractionation have been developed to increase the proteome coverage or to analyze specific subsets of the proteome. These include methods of fractionation and specific tagging procedures for labeling phosphoproteomes.

Owing to its use of volatile solvents, reverse phase high performance liquid

chromatography (RP-HPLC) is particularly compatible with mass spectrometry and is readily interfaced via a standard ESI source (LC-MS). The mass spectrometer is able to sample and analyze the peptides as they elute sequentially from the chromatographic column. While this approach has disadvantages of being slower than MALDI-based approaches, it has the advantage of generating higher quality data.

For extremely high resolution of very complex mixtures, use of two-dimensional chromatography techniques coupled to tandem mass spectrometry (LC/LC-MS/MS), sometimes referred to as *multidimensional protein identification technology* (MudPIT), has been established. The first dimension is often ion exchange chromatography followed by RP-HPLC for the second dimension. Progress in the development of LC/MS-based proteome analysis has raised the realistic prospect of nongel-based global protein expression profiling. Intact proteins are not readily amenable to RP-HPLC in complex mixtures and so it is necessary to predigest the proteins to peptides for analysis. This creates an added dimension of complexity and often precludes adequate analysis of posttranslationally modified proteins. While this technology is still evolving, it offers potential advantages in overcoming the limitations discussed above that are associated with 2-DE approaches. Recent advances have shown that the peptide retention time by LC, the m/z value and its intensity may provide sufficient information to both quantitatively and qualitatively identify a protein in a complex mixture.

2.3 Isotope Coding

Mass spectrometry has utilized stable isotopes to quantify relative amounts of individual analytes for many years. Attempts to perform experiments on a global proteomic scale have led to a number of exciting developments. These include the use of stable isotope labeling of amino acids in culture (SILAC) and other metabolic labeling techniques. However, for *in vivo* and larger studies, labeling at the point of analysis is needed. Digestion of proteins with trypsin produces neotermini on the peptides, which provide the opportunity for differential labeling with the isotopes ^{18}O and ^{16}O derived from heavy and light water respectively. The use of isotope-coded affinity tags (ICAT) has gained some acceptance in the last few years, with one notable early study showing differential protein expression in yeast grown under different metabolic conditions.

ICAT probes are a series of labeling reagents containing an affinity tag (biotin), a spacer labeled with a light or heavy isotope, and a thiol-specific reactive group (-iodo) for labeling of cysteine-containing peptides. Labeling is optimized to permit quantitative analysis of samples (Fig. 3). Early ICAT reagents possessed spacers containing either eight deuteriums (D8, the heavy isotope) or eight hydrogens (D0, the light isotope). Two samples are labeled, one with the light reagent and the other with the heavy reagent and the samples are then combined. Once digested, separated, and analyzed by mass spectrometry, the relative abundance of the isotope tags may be used to estimate the relative levels of the individual protein species.

In the earlier incarnation of ICAT, the necessity for high-resolution LC systems to resolve the plethora of peptides resulted in the undesired resolution of the light D0 and heavy D8 form. This is problematic as the mass spectrometric analysis

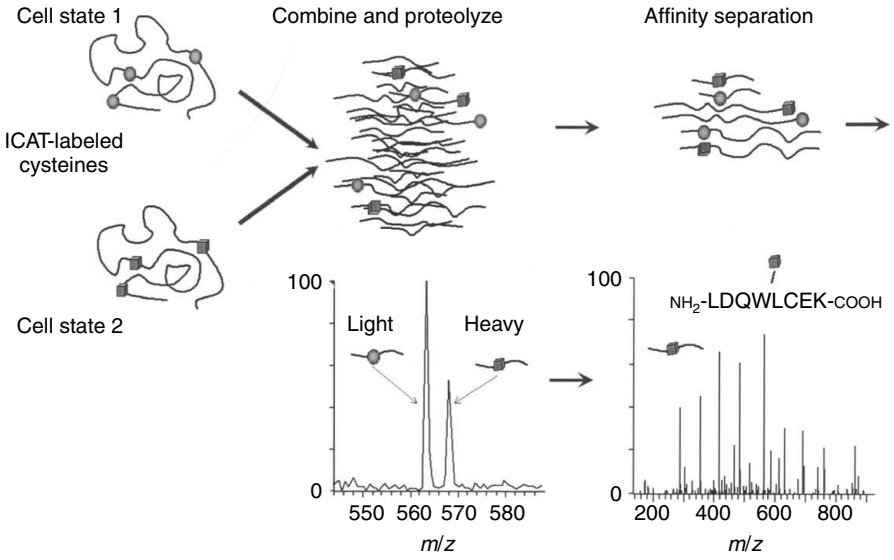

Fig. 3 Principle of isotope-coded affinity tagging. The proteins of two samples are labeled with a tag containing one of two isotopic labels such as eight deuteriums (squares) or eight protons (circles). The samples are combined, affinity separated, and analyzed by mass spectrometry. The relative abundance of the ions with the appropriate mass difference (e.g. 8Da) reflects the relative abundance of the proteins.

is predicated on the two ions entering the mass spectrometer at the same time. The affinity tag specificity for the cysteine residue also limited its applicability only to cysteine-containing proteins. In addition, the reagent itself did not perform ideally in the mass spectrometer, generating heterologous fragmentation, which confounded interpretation. Many new isotopes are being developed today, and it is hoped that future iterations will address these caveats.

2.4 Yeast Two-hybrid Systems

The yeast two-hybrid system identifies putative binary protein interactions, which, if proven, can provide powerful insights into biological pathways. The gene coding region for a protein of interest or part of a protein of interest (the ''bait'') is fused to the coding region for the DNA-binding domain of a yeast transcription factor (commonly GAL4 or LexA). This is engineered to ensure that the resulting fusion protein is targeted to the nucleus with a selection marker. The coding region for a single protein (the ''prey'') or a library of proteins from different tissues (''prey'' library) is fused to the transcriptional activation domain of the same transcription factor, and also targeted to the nucleus. Screening is performed with reporter genes under the control of a promoter that respond to the reconstituted DNA binding/transcription factor activity, reflecting bait–prey interaction (Fig. 4). Common reporter genes include enzymes, which support cellular growth *(LEU2, HIS3)* and β-galactosidase, for which a simple colorimetric detection is possible.

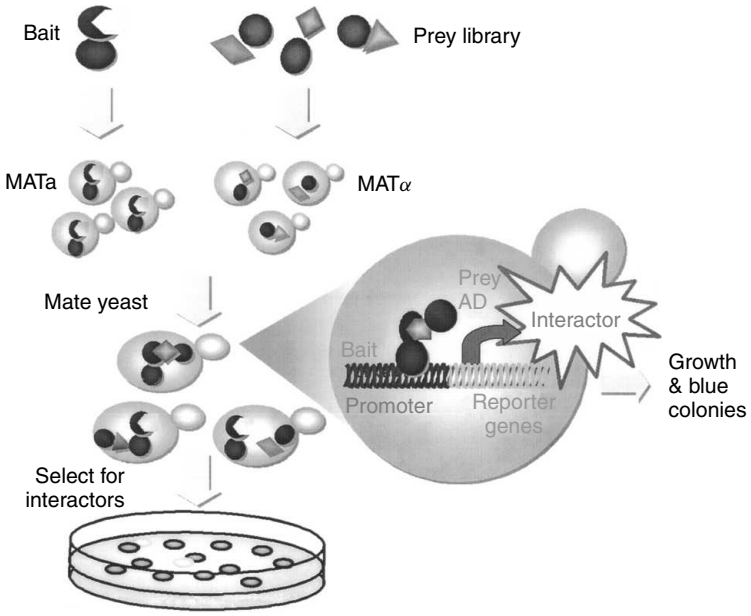

Fig. 4 Principle of the yeast two hybrid system for defining protein–protein interactions. Two chimeras, one containing a DNA-binding domain and the other an activation domain are cotransfected into yeast. If the fusion partners interact, the binding domain and activation domain are brought into proximity and activate transcription of a reporter gene.

In addition to screening prey libraries for interactors, the system can also be used for screening deletion mutants or polymorphisms to characterize the interacting domains. Variants of the yeast two-hybrid technique include yeast one-hybrid systems for protein-DNA interactions and yeast three-hybrid systems for looking at three way protein interactions or protein–drug interactions.

Although there is an association between the strength of the interaction and the level of reporter activity in the yeast two-hybrid system, the interaction is only weakly quantitative and the true strength of the technique is in its qualitative analysis. Although false-positive results due to nonspecific interactions or spontaneous transactivation activity are often likely to confound interpretation, careful experimental design and interpretation as well as follow-up with directed confirmation assays using alternate methods (e.g. coimmunoprecipitation) can help with the identification and validation of true interactors. Often critical protein–protein interactions are specific to a disease state and so the yeast model may generate false-negative data. Other limitations of the technology include aberrant interactions owing to improper folding, difficulty with finding membrane protein interactors, lack of necessary posttranslational modifications, or inappropriate cellular compartmentalization. However, it has the tremendous advantage of being cheap and simple to run, is an *in vivo* system, and can be run on a high-throughput scale. The positive aspects are reflected in its wide utility and role in many important discoveries including

the GABA-B receptor heterodimerization and producing genome scale interaction maps for *Saccharomyces cerevisiae* (yeast), *Caenorhabditis elegans* (worm), and *Drosophila* (fruit fly).

2.5 Protein Arrays

Protein arrays constitute an emerging technology, which permits the analysis of protein expression, protein interactions, or protein function. The microarray-like format permits the deposition of various biomolecules onto a solid surface in an ordered array (Fig. 5). Antibody chips allow the detection of protein expression in an analogous method to enzyme-linked immunoassays (ELISAs). Arraying of functional biological molecules will also permit protein interactions as well as protein function to be investigated.

The inherent promise of protein arrays is the capacity to perform routine assays in a multiplexed format. This should greatly improve the comparative nature of a study by reducing assay-to-assay variability. Another benefit in practical terms is the reduction in reagent usage, which has clear relevance for the analysis of scarce clinical samples. Despite these advantages, the performance of protein expression arrays appears to be comparable in terms of sensitivity to ELISAs rather than enhanced. Certain techniques are being developed to try and increase sensitivity, including the use of novel detection systems (e.g. resonance light scattering) and signal amplification systems, but the results to date remain equivocal. Future developments using more advanced detection systems such as mass spectrometry may offer increased sensitivity, although for many applications such as expression analysis, this must be achieved while retaining

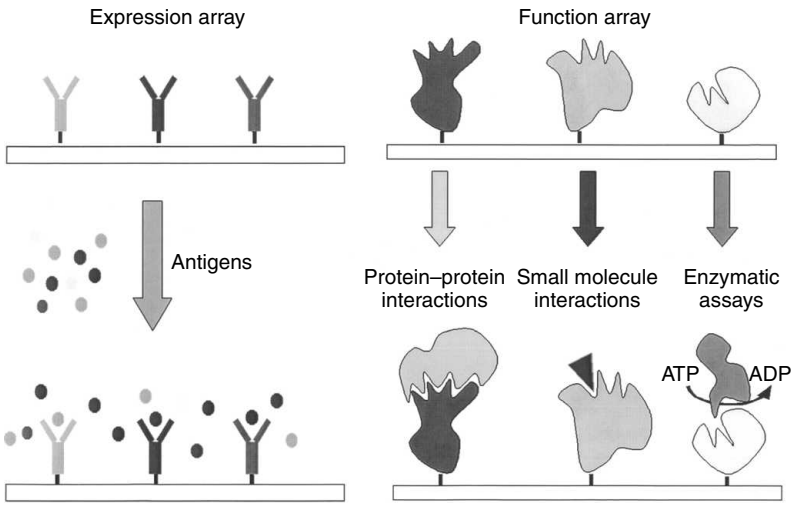

Fig. 5 Protein arrays contain a defined set of proteins arrayed at high density, typically onto a solid surface. Protein arrays can be used for protein profiling by immobilization of antibodies to specific analytes or as functional arrays for detecting protein–protein or protein–drug interactions. Proteins have also been arrayed to detect and characterize the functionality and specificity of both enzymes and substrates.

quantification. Also, as with other ''omic-based'' technologies, such advances will place demands upon the bioinformatics tools needed to manage and interpret the data.

Currently, the multiplexed protein array assay cannot, in general, compete with individual assays in terms of performance. Although the technology is advancing rapidly with respect to surface chemistry, detection, and data analysis, the limitations of the technology are predominantly in reagent supply. Commercial antibodies with the required sensitivity and selectivity are not available for the vast majority of proteins, and, even where they do exist, only 5% or less are suitable for use in protein arrays, having been produced for other purposes such as immunohistochemistry and western blotting. The production of antibodies is both labor intensive and time consuming. For example, production of monoclonal antibodies requires immunization, generation of hybridoma cell lines, and antibody isolation. The end result is often an antibody that can be thoroughly characterized in terms of sensitivity and selectivity, and a renewable source for producing this antibody over and over again. Although the use of phage libraries and other more novel capture reagents exist, such as aptamers and proteins based on novel scaffolds, the evidence is that maturation is needed to achieve ligands of acceptable performance and assay screening of potential reagents is often rate-limiting. The same challenge is true for functional proteins where the promise of whole genome or near whole genome cloning and expression is still to be realized. Future developments in capture reagents and protein production are likely to control the rate at which omic-scale protein arrays impact the biomedical sciences. Despite the current limitations, protein arrays for specific applications remain an exciting prospect and are beginning to yield useful and meaningful results.

2.6 Bioinformatics

A robust and expert bioinformatics platform is a key requirement for the capture, organization, analysis, and storage of proteomics data. The aim of both transcriptomics and proteomics studies is to generate high quality quantitative expression data. This needs to be managed in such a way as to enable information to be derived about complex patterns of expression and pathways consistent with pathology, physiology, drug efficacy, toxicology, and so on. By necessity, bioinformatics is a cross-disciplinary activity embracing computer science, software engineering, mathematics, and biology. The massive leap in scale accompanying ''omic'' technologies has necessitated ever more sophisticated bioinformatic tools to support target selection and validation, and disease understanding. The ability to relate a small piece of information on protein sequence to enable gene identification is critical and fundamental to proteomics, but increasingly important is the ability to place expression changes and interactions into a biological context of pathway and function. A concerted effort has begun to emerge to store, analyze and disseminate proteomic information, although it is still a discipline in its infancy where additional progress is eagerly awaited.

Many searchable databases available on the World Wide Web are being constantly updated to incorporate the increasing volume of data being generated from diverse genomic and proteomic platforms. Placing proteins in their correct functional

and biological context is likely to be a complex process with lessons to be learnt from transcriptomics and other disciplines.

3 Applications

3.1 Target Identification and Validation

Since proteins are the ultimate structural and functional components of life, understanding biological systems at the protein level is critical to delineating biological pathways, including those involved in disease as well as determining how drugs exert their beneficial and sometimes toxic effects. These explorations can lead to the identification of new targets (also proteins to be avoided) as well as contributing to validating the involvement of the particular protein involved in the biology of the disease. Proteomics has therefore begun to provide insights into several areas of medical research.

In the field of infectious diseases, proteomics – in conjunction with other disciplines such as transcriptomics and RNA interference (RNAi) – has been used to unravel the mechanism of certain drug activities and to define host–pathogen interactions. This holds the promise of providing new methods for diagnosing and treating infectious diseases. Initial studies focused on the effect of bacterial infection within host cells, including analysis of those proteins that are selectively expressed by the pathogen during infection. These studies also led to increasing our understanding of the inflammatory signaling networks in the process of sepsis. More recent work has focused on the mechanisms of pathogenesis. In addition, work with organisms such as *Plasmodium falciparum*, the malaria parasite, has provided critical insights into major diseases such as malaria, via delineation of the protein expression patterns at distinct stages in the life cycle of the parasite.

Protein changes correlating with disease processes, such as inflammation, have indicated dysregulation of proteins, which may subsequently be modulated by non-steroidal anti-inflammatory drugs. These included a time- and gender-dependent upregulation of acute phase proteins in a rat model. Respiratory diseases, such as chronic obstructive pulmonary disease and asthma, are known to have a strong inflammatory element to their pathology. Genetics has greatly advanced our understanding of the pathobiology underlying complex genetic disorders such as asthma, with numerous genetic loci and individual genes showing a linkage or association. Proteomics has the ability to complement these genetic results by generating biomarkers that may prove invaluable as prognostic tools for predicting asthma susceptibility and disease severity as well as predictors of drug response. As part of the drive to deliver such biomarkers, proteomics has been applied to a number of biofluids, such as bronchoalveolar lavage, together with plasma and serum.

Proteomics has also been deployed to widen the understanding of the therapeutic value of vaccines. For example, in a relatively sophisticated approach to define novel vaccine candidates, 2-DE has been incorporated into studies to define immunogenic proteins, which elicit a host response. This has been reported for therapeutic areas as diverse as infectious diseases and oncology. The latter raises the prospect of developing future cancer vaccines, making provision for a major unmet therapeutic need. Similar approaches have

been applied to advancing the diagnosis and treatment of transplant rejection via identification of early events in the process of rejection.

Research in cardiovascular biology in the pregenomic era focused on classical pathophysiological descriptions, with the later incorporation of receptor biology and signal transduction–driven approaches. Cardiovascular research is a discipline for which there are many *in vitro* and *in vivo* model systems available, which provide a vehicle for a more detailed understanding of the molecular basis of disease. In the postgenomic era, proteomics will provide an important role, bridging the gap between genetic and physiological research. Atherosclerosis is a disease of the cardiovascular system, which is now generally accepted to have a large inflammatory component. Several risk factors have been identified including cell adhesion molecules and inflammatory markers such as C reactive protein. Proteomics has recently been instrumental in discovering several putative protein markers associated with atherosclerosis, many of which have a recognized role in inflammation.

Applications of proteomics in the field of oncology are quite diverse, focusing on advancing the understanding of mechanisms, diagnosis, and prognosis, as well as defining possible therapeutic regimes in a number of cancers. One important role has been to advance the definition of mechanisms underlying cellular regulation, including those implicated in the transcriptional regulation of metastasis. Protein expression in hepatocellular carcinoma cell lines, which has proven to be a useful model of persistent viral hepatitis–induced hepatoma, has revealed interesting new proteins and confirmed others previously implicated in the disease. Proteomics has also been used to gain a better understanding of the multifactorial nature of chemoresistance demonstrated by certain cancer cells. The oncology area has been extensively studied using DNA chips (microarrays) for transcript analysis, hence there is a wonderful opportunity for synergy between transcriptomics and proteomics by comparing and contrasting the data for validation of new targets or new disease diagnostic or disease/drug prognostic markers.

In the fields of neurology and psychiatry, the understanding of neurologically relevant systems has been enhanced by significant progress in mapping the human brain proteome. This has been further advanced by the investigation of model organisms such as the mouse and *in vitro* cell systems such as synaptosomes. Alzheimer's disease is a complex genetic disorder in which dysfunction is associated with mutational loci (amyloid precursor protein, presenilin 1 and presenilin 2) as well as susceptibility loci (apolipoprotein E). Progress has been made in this area by detection of oxidatively modified proteins consistent with previously identified peroxynitrite-mediated damage and oxidatively modified RNA. Analysis of human postmortem brains from both Alzheimer's and Down syndrome patients indicates decreased levels of proteins such as synaptosomal-associated protein 25 (snap 25), possibly reflecting impaired synaptogenesis or neuronal loss. Postmortem studies and antemortem analysis of cerebrospinal fluid have also revealed several additional proteins found to be altered in expression in Alzheimer's disease, including apolipoprotein E.

In psychiatric research, the application of genomics and proteomics to disorders as diverse as depression, schizophrenia, and autism is being considered as a major

potential contributor in terms of disease diagnosis, understanding, and therapy. New avenues into disease understanding have been illuminated by genetic studies, for example, the discovery of neuregulin, DAOO, and G72 (the latter two associated with glutamate pathways) as schizophrenia susceptibility genes. To date, analysis of cerebrospinal fluid from schizophrenics has produced limited identifiable changes in protein expression and in general, validated markers of psychiatric disorders remain elusive. Despite this difficulty, it is likely that given clinical material of sufficient quality and with detailed disease phenotypic data, proteomics can make a major contribution to both mechanistic understanding and diagnosis.

3.2 Protein–protein Interactions

A key aspect of understanding biological systems is to gain an insight into protein function. Characterizing protein function in a normal state and defining changes in function in the dysregulated state associated with disease can be extremely challenging and while expression proteomics is certainly capable of providing important clues into protein function, investigation of how proteins interact with one another is of additional utility. Association of a protein of unknown function with proteins of known function or linkage to a defined pathway can be invaluable in delineating cellular processes and disease mechanisms.

Various methods exist for defining protein interactions including the yeast two-hybrid system and affinity pull downs or chemoproteomic approaches. In a relatively recent advance in chemoproteomics, a tandem affinity purification (TAP) tag is used in which a fusion of the binding domains of both protein A and calmodulin are employed to enhance selectivity. The two affinity regions are separated by a cleavable tobacco etch virus protease cleavage site. This approach has been applied successfully to create a functionally organized database for yeast–protein interactions, and provide the first insight of how a complex network of proteins may operate in a eukaryotic proteome.

Yeast two-hybrid systems have also been effective in defining new protein targets for pharmaceutical intervention including defining novel nuclear hormone receptors and their cofactors and in characterizing the specific residues or domains within proteins associated with protein function. For instance, the system has also been employed to find peptides, which bind and inhibit key enzymes such as kinases.

As described above, protein arrays are now being developed to define protein function and studies in yeast have already defined and characterized novel binding motifs for proteins such as calmodulin. Perhaps the most immediate benefit of protein interaction studies will be the assembly of large databases of hitherto undefined pathways, which will assist in associating proteins with their functions or, more broadly, with specific pathways and cellular processes.

3.3 Protein Biomarkers in Clinical and Preclinical Research

The discovery and successful application of therapeutic treatments to diseases is a very complicated and lengthy process. Through the development cycle of a new drug candidate, a vast number of hurdles need to be overcome. They mainly involve a clear establishment that the proposed molecule

is safe, tolerable, and therapeutically efficacious. During the process, the compound has to be carefully and thoroughly tested in preclinical animal models, and only if those studies are successful in demonstrating the above attributes will the drug progress to tightly controlled human trials. The complexity, scientific rigor, and vast amount of human and financial resources needed during the drug discovery and development process mean that finding ways to predict, diagnose, and understand better the manifestations of disease as well as the outcome of the proposed drug treatment are critical factors to be addressed.

Alongside transcriptomics and metabolomics, proteomics has the potential to dramatically improve the speed of clinical research, discriminating between diseases and disease subtypes. Proteomics applied to biofluids such as plasma offers a relatively noninvasive method of providing bedside/near bedside clinical support. In particular, proteomics has major potential for finding novel biomarkers that can act as predictive signatures of disease onset and progression, act as surrogate markers of therapeutic efficacy, or reveal potential toxicology. The search for novel protein biological biomarkers that can predict at an early stage the efficacy and safety profiles of a drug has benefited from a concerted and vigorous increase in effort in the last decade.

Proteomics technologies are playing a key role in the search for biomarkers, often complementing other approaches such as transcriptomics and genetics. While acknowledging recent advances, initial progress in plasma/serum proteomics was slow owing to the complexity and wide dynamic range of the protein content. For example, while the concentration of serum albumin in normal plasma is in the range of $35–50\,mg{\cdot}mL^{-1}$, the concentration of a cytokine such as interleukin IL6 is 10^9 times lower at $0–5\,pg{\cdot}mL^{-1}$. Methods for removal of albumin and other abundant proteins from plasma have now dramatically improved the scope for clinical proteomics in biofluids. In both preclinical as well as clinical arena, the use of 2-DE gel electrophoresis techniques in conjunction with mass spectrometry as well as the use of immunobased approaches is now providing important and useful data.

Adverse drug reactions are a significant issue both in terms of molecules failing both in preclinical development and in the clinic. Since the estimated cost of bringing a drug to the market is $800 million, any improvement in attrition rates, however small, will accrue significant benefits both to pharmaceutical companies and also to the patients themselves. Initially, the focus of genomic technologies in the area of toxicology was centered on transcriptomics, with the analysis of RNA expression in tissues obtained from animals treated with test compounds. However, the parallel analysis of genes and proteins has brought new insight to both *in vitro* and *in vivo* studies with the goal to predict the toxic effects of potential of new potential drugs much earlier in the development cycle. The aim of predictive toxicology via proteomics is to improve lead and candidate selection and enhance drug efficacy and safety monitoring via profiling of defined surrogate markers from easily obtainable biofluids. Proteomics via 2-DE enables drug-related alterations in expression profiles to be compared and potential biomarkers for further scrutiny to be identified. Several studies have already begun to define protein expression changes, which correlate with drug-mediated toxicity, whereas specific studies have indicated possible mechanisms of toxicity.

Recently, the surface-enhanced laser desorption ionization (SELDI™) time of flight (TOF) technology has been developed. Proteins in a mixture are selectively bound to a surface of defined chemistry and their masses profiled by mass spectrometry. Although the identity of the proteins cannot usually be ascertained from this type of data, a specific mass spectrum can be obtained and used to characterize a specific analyte. This has been applied to define potential biomarkers of ovarian, breast, and prostate cancer.

Application of ''omic''-based technologies can offer additional insights over and above the growing area of pharmacogenetics. Pharmacoproteomics represents a more phenotypic approach to the analysis of patient-to-patient variability than is provided by genotyping as it will assess the effects of an individual's genetic makeup as well as the influences of the environment and lifestyle. This makes proteomics a valuable tool in disease diagnosis and the push toward defining subgroups of patients who are more suited to the individual therapies.

4 Future Perspectives

4.1 Toward a Full Proteome Map

The genomes of higher eukaryotes give rise to proteomes of high complexity owing to the predominance of posttranslational modifications and splice variants. Indeed, the level of complexity appears to correlate with that of the organism. It has been estimated that the number of proteins per gene is around 1.1 to 1.3 for bacteria, 3 for yeast and around 10 for humans, although these are estimates and may only hint at the actual levels of complexity.

In addition, the true relevance of a protein function cannot be derived from information about a single protein in isolation. The activity of a given protein will be strongly influenced by its tissue distribution and intracellular localization, as well as its proximity to and interaction with other proteins and metabolites. These factors illustrate the increasing need to move the technology toward total proteome coverage.

Although a laudable aim, currently no method is in sight that will allow the analysis of the entire proteome. Progress toward significantly higher proteome coverage is being made via prefractionation techniques to analyze subproteomes. Several studies have now analyzed proteomes at the organellar level and even at the suborganellar level. This contributes more information about the location, expression, and function of proteins, and these methods for analysis are becoming increasingly sensitive, robust and quantitative. Historically, certain types of proteins have been difficult to study, including highly hydrophobic membrane-bound proteins. Although membrane proteins have been typically underrepresented during analysis by 2-DE, progress in extraction methods for membrane proteins and the introduction of improved solubilization techniques, both in sample preparation and separation, have markedly improved membrane protein detection. In addition, the ability to select individual protein classes such as glycosylated proteins or phosphoproteins via antibodies or specific tags has increased the scope and range of proteome subset analyses. Advances in the technology and, in particular, the recent advances in nongel-based proteomics may

herald a major advance toward increased proteome coverage.

4.2 Biological Validation of Protein Functions

As mentioned a number of times in this review, proteomics offers tremendous opportunities to rapidly progress biological and medical research. The ability to analyze and potentially quantify many proteins at once in a multiplexed assay without any preselection makes proteomics a truly open multiplexed discovery platform. However, experience to date has shown that the wealth of information created can be extremely difficult to process and presents a number of novel issues. The multiplexed nature of the assay increases the chances of discovering many proteins associated with a pathology or biological phenotype. It also increases the probability of identifying changes, which occur purely by chance, or as an indirect result of the up- or downregulation of relevant proteins. Thus, the necessity for rigorous validation of protein changes associated with altered phenotypes is of paramount importance and places a large burden on what is currently a potentially resource and rate-limiting step.

While many proteins such as enzymes can be assayed functionally when defined substrates are available, individual immunoassays have long been one of the definitive approaches to measuring individual protein expression. However, as discussed above, the limited availability of high-quality antibody reagents has led to significant effort being expended on provision of antibody reagents for assays and protein arrays. Further, the creation of international consortia is being proposed to undertake and complete the monumental task of producing antibodies against every human protein. Additional validation can also be gleaned from specific pathway expansion, gene silencing and gene knockout experiments.

4.3 Clinical and Diagnostic Applications

A number of issues need to be addressed before proteomics can achieve general and routine applicability in clinical studies. In addition to the caveats of working with plasma and serum, as discussed above, there are issues surrounding the heterogeneous nature of human samples. Biological systems are complex and study populations from clinical cohorts tend to be highly variable. Many clinical studies are derived from populations representing diversity in genetic and environmental and lifestyle factors, as well as in age, disease severity and comorbidity. All of these factors conspire to confound interpretation of clinical proteomic data. The capacity to run proteomic analysis at a scale consistent with large populations is needed to facilitate extraction of biologically and statistically significant information from the confounding elements. The industrialization of 2-DE is not as advanced as is needed to address very large clinical cohorts, although it is now capable of processing thousands of samples. The immediate promise of the emerging techniques such as LC/LC-MS/MS and protein arrays will be to augment information content attainable with 2-DE rather than to provide dramatically increased throughput.

Progress to date in the area of clinical proteomics has been rapid and it will surely continue to improve at an equally impressive rate given the huge demand and benefits. The potential for defining

biomarkers for therapeutic or diagnostic use, as well as defining biological mechanisms is immense.

Acknowledgments

The authors wish to thank Jingwen Chen, Bob Hollingsworth, Arthur Moseley, Ian White, and Julia White for their help in preparing the figures, and Mike Trower and Mark Skehel for helpful comments on the manuscript.

Keywords

F_0F_1
ATP synthase or proton-translocating ATPase formed from membrane extrinsic (F_1) and intrinsic (F_0) sectors. Nomenclature from factors of oxidative phosphorylation.

F-ATPase
One of the three classes of ion transport ATPases, mostly proton-translocating ATPase. Nomenclature from F_0F_1 or factors of oxidative phosphorylation.

P-type ATPase
Ion transport ATPase forming acylphosphoenzyme intermediates during catalysis. This group contains proton-translocating ATPases such as H^+/K^+ ATPase and H^+ATPase. They are different from F-ATPase, or V-ATPase, but similar to Na^+/K^+ ATPase.

Rotational Catalysis
Continuous rotation of $\gamma\varepsilon$ C_{10} subunit complex during ATP synthesis or hydrolysis by F-ATPase. Similar mechanism found in V-ATPase.

γ-Subunit
F-ATPase subunit located at the center of the catalytic hexamer ($\alpha_3\beta_3$) formed from the α- and β-subunits, and rotating during catalysis.

V-ATPase
Vacuolar-type proton-translocating ATPase. Nomenclature from a proton pump identified initially in fungal or plant vacuoles, but now found in a wide variety of endomembrane organelles such as lysosomes and endosomes and plasma membrane of specialized cells such as osteoclast or kidney intercalated cell.

Abbreviations

DCCD: dicyclohexylcarbodiimide
Pi: inorganic phosphate

Proton-translocating ATPases synthesize or hydrolyze ATP coupling with electrochemical proton gradient, and have important roles in animal and plant physiology. The ion transporting ATPases are classified as F-ATPases (F-type ATPases), V-ATPases (V-type ATPases), and P-ATPases (P-type ATPase). The F-ATPase, also called *ATP synthase*, is found in chloroplasts, mitochondria, or bacterial membranes, and synthesizes most of the ATP, the biological energy currency. The enzyme is formed basically from eight subunits, *a*-, *b*-, and *c*-subunits forming membrane intrinsic F_0 sector with ab_2c_{10} stoichiometry, and α-, β-, γ-, δ-, and

ε-subunits forming peripheral F_1 sector with $\alpha_3\beta_3\gamma\delta\varepsilon$ stoichiometry. Three catalytic β-subunits forming a hexamer with α-subunit ($\alpha_3\beta_3$) have catalytic cooperativity. The $\gamma\varepsilon c_{10}$ subunits complex, formed from peripheral ($\gamma\varepsilon$) and intrinsic membrane (c) subunits is a cential stalk, rotating during catalysis. The V-ATPase forms inside acidic pH in endomembrane organelles such as lysosomes, endosomes, synaptic vesicles, and so on, and is similar to F-ATPase in subunit organization and structure. The same enzyme is found in plasma membrane of special cells such as osteoclast and kidney intercalated cell. Gastric proton pump H^+/K^+ATPase or plant plasma membrane H^+ATPase belongs to P-ATPases forming acyl phosphate intermediate, and is not discussed in this article.

1 Introduction

The mechanism of ATP synthesis has been a focus of biochemists for more than four decades. ATP synthase was first identified in the mitochondrial inner membrane, and then found successively in chloroplasts and bacterial membranes. This enzyme synthesizes ATP from ADP and phosphate (Pi) coupled with an electrochemical proton gradient, and is also called *proton-translocating ATPase* or F-ATPase (F-type ATPase) because of the reversible proton pumping upon ATP hydrolysis. The name F-ATPase originated from the coupling factor of oxidative phosphorylation sensitive to oligomycin. *Escherichia coli* F-ATPase is composed of a membrane extrinsic F_1 sector and a transmembrane F_0, formed from five ($\alpha_3\beta_3\gamma\delta\varepsilon$) and three ($ab_2c_{10-14}$) subunit assemblies with different stoichiometries, respectively (Fig. 1). It can also be divided into a catalytic $\alpha_3\beta_3$ hexamer, stalks ($\gamma\varepsilon ab_2$), and membrane (ab_2c_{10-14}) domains. Two stalks (central and peripheral stalk) have been observed by electron microscopy. The mitochondrial enzyme has additional subunits, possibly with regulatory functions.

The higher-ordered X-ray structure of the bovine $\alpha_3\beta_3\gamma$ complex had been solved in 1994 by John Walker and coworkers. Following this breakthrough, the structures of crystals of bovine F_1, inhibited by efrapeptin, aurovertin, NBD-Cl (7-chloro-4-nitrobenzo-2-oxa-1,3-diazole), and DCCD (dicyclohexylcarbodiimide) were solved by the same group. Bovine F_1 containing 1 mol MgADP trifluoroaluminate and 2 mol MgADP trifluoroaluminate has also been crystallized, and the structures have been determined. These studies, together with biochemical analysis, have contributed greatly to an understanding of the catalytic site and mechanism. The structures of F_1 sectors of other origins have also been reported.

The catalytic site is mainly located in the β-subunit of the $\alpha_3\beta_3$ hexamer, and the three sites (one in each β) show strong cooperativity. The amino- and carboxyl-terminal helices of the γ-subunit are located in the center of the $\alpha_3\beta_3$ hexamer, and form a central stalk with the ε-subunit. The peripheral or second stalk is formed from the *a*- and *b*-subunits, and the δ-subunit is located near the top of the α-subunit. The proton pathway is located at the interface between

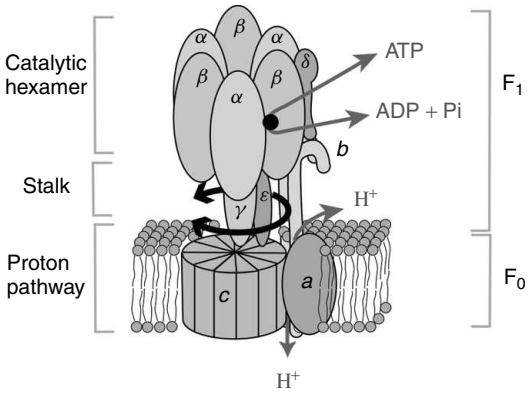

Fig. 1 Schematic model of proton-translocating F-ATPase, showing the subunit structures of the catalytic hexamer ($\alpha_3\beta_3$), stalk and membrane domain. The membrane extrinsic F_1 and transmembrane F_0 sector are shown together with energy coupling between the ATP synthesis–hydrolysis and subunit rotation.

the *a*- and *c*-subunits, and the hairpin structure of the purified *c*-subunit has been solved by Fillingame and coworkers using NMR. A ring structure formed from multiple *c*-subunits was suggested by early studies involving electron and atomic force microscopy, and was extensively analyzed recently through NMR structure and genetic approaches. The X-ray structure of yeast F_1 with a *c*-subunit ring has also been reported by Stock et al.

The mechanism of coupling of proton transport and ATP synthesis or hydrolysis has been a major question for this complicated enzyme. The binding change mechanism proposes rotation of the γ-subunit relative to the $\alpha_3\beta_3$ hexamer coupled with the chemistry at the catalytic sites. Rotation of the $\gamma\varepsilon c_{10-14}$ complex relative to $\alpha_3\beta_3\delta ab_2$ upon ATP addition was shown recently, indicating that continuous rotation of the assembly of F_1 and F_0 subunits is involved in the coupling between ATP hydrolysis and proton transport.

Vacuolar-type ATPase (V-ATPase) with significant similarity to F-ATPase was introduced later to a family of proton-translocating ATPases. V-ATPase is apparently different from F-ATPase in its physiological roles, and forms an acidic luminal pH in endomembrane organelles including lysosomes and endosomes, and in extracellular compartments such as resorption lacuna formed between osteoclasts and the bone surface. It has extrinsic membrane V_1 and V_0 transmembrane domains formed from the *A*, *B*, *C*, *D*, *E*-, *F*-, *G*-, and *H*-subunits, and *a*, *c*, *c′*, *c″*, and *d*, respectively. F- and V-ATPase share significant homology, especially in its catalytic subunits and proton pathways, and also share some unique differences, including its membrane sector and stalk region subunit compositions. A series of isoforms have been found for V-ATPase subunits. Thus, comparative studies of the two proton–translocating ATPases are pertinent for understanding the molecular mechanisms of both.

In this chapter, we discuss recent progress made in the understanding of F-ATPase, focusing mainly on the energy coupling between the chemistry and proton transport through subunit rotation, and also discuss V-ATPase from a similar aspect. It should be interesting for readers to follow a series of biochemical studies to show rotational catalysis of the F-ATPase holoenzyme leading to that of the V-ATPase.

2 Catalytic Mechanism of Proton-translocating F-ATPase

As expected from its complicated structure, F-ATPase is not a simple Michaelis–Menten type enzyme. Furthermore, the overall mechanism includes catalysis (chemistry), subunit rotation and proton translocation. X-ray structure and kinetic studies, especially substrate binding analysis with an intrinsic tryptophan probe, revealed that the three catalytic sites are asymmetric. Senior and coworkers have recently discussed and summarized the molecular catalytic mechanism of F-ATPase.

ATP synthesis and hydrolysis could be carried out kinetically at a single site (unisite catalysis), two sites operating together (bisite catalysis), or all three sites working together (trisite catalysis). Unisite catalysis has only been demonstrated for ATP hydrolysis, and can be measured experimentally with an ATP:F_1 ratio of less than 1 : 3. This rate is 10^5–10^6-fold lower than that of steady state (multisite) catalysis. The enzyme cross-linked chemically and thus could not rotate, but could still carry out unisite catalysis. This catalysis is not a part of the steady state, which includes subunit rotation.

Catalytic residues have been identified by analyzing unisite catalysis of the purified *E. coli* mutant F_1 sector (Fig. 2). Briefly, βLys155 of the β-subunit is required for binding of the γ-phosphate moiety, as shown by studies involving affinity labeling and mutant enzymes such as βLys155Ala (βLys155 → Ala) or βLys155Ser. The βArg182 residue is also involved in the binding. Enzymes with substitutions of βThr156 showed similar properties to those of βLys155. The hydroxyl moiety of βThr156 is essential, possibly for Mg^{2+} binding, since it can only be replaced by a serine residue. βGlu181 is a critical catalytic residue. Its side chain forms a hydrogen bond with a water molecule located near the γ-phosphate of ATP. However, it was shown later that this residue was not involved in nucleotide binding or Mg^{2+} coordination. βTyr331, which is stacked close to the adenine ring, is required for the binding of ADP or ATP. Results of analysis of the tryptophan fluorescence of the βTyr331Trp mutant F_1 are consistent

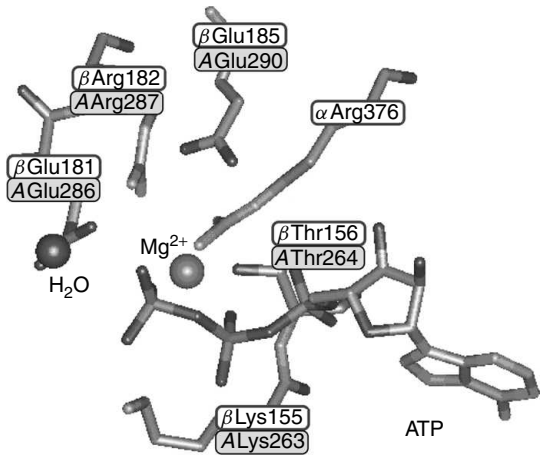

Fig. 2 Catalytic sites of F-ATPase and V-ATPase. The catalytic residues of *E. coli* F-ATPase are shown together with bound ATP. Their positions are cited according to the bovine crystal structure. Corresponding residues of yeast V-ATPase are also shown.

with the role of the βTyr331 residue. The bovine residues corresponding to those discussed above are located close to the phosphate moiety or the adenine ring of bound ATP or ADP as shown in the X-ray structure (Fig. 2).

Recent results, including the F_1 structure of all three sites filled with nucleotides, support trisite catalysis, in which the three sites are working together during the steady state, and the notion that bisite catalysis does not occur. We leave convincing discussions of these points to the article of Senior and coworkers.

It can be assumed that mutant enzymes defective in steady state catalysis should show impaired unisite catalysis. In this regard, αArg376 mutant enzymes are of interest. The αArg376 residue of the α-subunit is located close to the β- or γ-phosphate of ATP or ADP and Mg at the catalytic site (Fig. 2). However, αAg376 does not directly participate in the chemistry of ATP hydrolysis or synthesis, as shown by the unisite catalysis of mutant F_1 sectors. The αArg376Lys or αArg376Ala mutant enzyme showed 2×10^3-fold lower steady state ATP hydrolysis than the wild type. However, the mutant enzymes showed essentially the same kinetics for unisite catalysis as the wild type, suggesting that they can pass through the transition state. These results indicate that αArg376 is essential for promotion of catalysis to the steady state turnover. This notion is different from the previously suggested roles of αArg376 that was deduced from the structural model and fluoroaluminate binding, an indicator of the formation of the pentacovalent transition state. The βGlu185 residue, located close to the γ-phosphate and Mg at the catalytic site, may have a similar role to αArg376 because the mutant enzymes maintain unisite catalysis, but are defective in multisite catalysis. However, detailed analysis could not be carried out because the mutant F_1 was unstable after solubilization from membranes.

The binding change mechanism of Boyer proposes that the three sites are involved sequentially in ATP synthesis or hydrolysis: at a specific point of time during the steady state, the chemical reaction occurs reversibly at one site and ATP release and/or binding of ATP + Pi occurs at the two other sites with the expenditure of energy. Evidence supporting catalytic cooperativity and the binding change mechanism has accumulated, as reviewed by Boyer in 1997. It includes early kinetic evidence of unisite and steady state catalysis showing three K_m values and three interacting nucleotide binding sites, ^{18}O isotope exchange reactions, inhibitor studies, and so on. These studies suggested that the chemistry, "ADP + Pi $\leftrightarrow$ ATP + H_2O," at the catalytic site is reversible, and provides essentially no energy change. The mechanism is strongly supported by the X-ray structure showing asymmetric catalytic sites and predicting continuous γ-subunit rotation. However, it cannot be concluded that the binding change mechanism was proven at the molecular level, although the mechanism is conceptually accepted and has been extremely useful for understanding the enzyme.

3 Roles of the γ-Subunit: Energy Coupling by Mechanical Rotation

3.1 Roles of the γ-Subunit in Energy Coupling

The essential role of the γ-subunit in catalysis and assembly was shown by early reconstitution experiments: a catalytic core

complex exhibiting ATPase activity could be reconstituted from the purified *E. coli* α-, β-, and γ-subunits, but not without the γ-subunit. Consistently, assembly of the F_1 sector is strongly affected by γ-subunit mutations, especially those of residues interacting with the β-subunit. The isolated $\alpha_3\beta_3\gamma$ complex could functionally bind to the F_0 sector only after its assembly with the δ- and ε-subunits. These results indicate that the two minor subunits are required for the functional binding of $\alpha_3\beta_3\gamma$.

Early genetic approaches focused on the γ-subunit carboxyl-terminal region. The amino acid sequences of the γ-subunits are weakly conserved among different species, though their X-ray structures are similar. When the known γ-sequences are aligned, only 28 of the 286 residues of the *E. coli* subunit are conserved, and mostly in the carboxyl- and amino-terminal helices located at the center of the $\alpha_3\beta_3$ hexamer. Seventeen residues are conserved between residues 242 and 286 of the γ-subunit. An enzyme lacking 10 residues at the carboxyl terminus is still capable of *in vivo* ATP synthesis, indicating that the three conserved residues in this region are not required. Structural flexibility of the carboxyl terminus was also demonstrated by a frameshift mutation: the enzyme was still active with the γ-subunit having seven additional residues at its carboxyl terminus together with nine altered residues downstream of γThr277.

The enzyme with the nonsense mutation (γGln269End) was inactive, and substitution of a conserved residue (γGln269, γThr273, or γGlu275) between γGln269 and γLeu276 gave enzymes with reduced ATPase activity and energy coupling. We noticed that mutations resulted in different ratios of ATPase catalysis and proton transport; three mutants (βThr277End, βGln269Leu, and βGlu275Lys) exhibited about 15% of the wild-type ATPase activity, but showed various degrees of ATP-dependent H^+ transport and *in vivo* ATP synthesis. These results suggest active role(s) of the γ-subunit in ATPase activity and energy coupling.

In addition to the carboxyl terminus, the only other conserved region is near the amino terminus. The importance of this region was first suggested by the mutant lacking residues between γLys21 and γAla27, which resulted in failure of assembly of the F_1 complex. We introduced amino acid substitutions systematically into the amino-terminal region of the γ-subunit. Most of the changes between γIle19 and γLys33, γAsp83 and γCys87, or at γAsp65 had no effect, even with a drastic replacement such as hydrophobic to hydrophilic or acidic to basic. Interesting exceptions were the γMet23Arg and γMet23Lys substitutions. These mutants grew only slowly on succinate through oxidative phosphorylation, indicating that they were impaired in ATP synthesis. However, the membranes prepared from the γArg23 and γLys23 strains showed 100 and 65% of the wild-type ATPase activity, but formed only 32 and 17% of the electrochemical proton gradient respectively, indicating that these mutants are defective in energy coupling between ATP hydrolysis and proton transport. In the X-ray structure, the γMet23 residue is located close to the DELSEED (βAsp380–βAsp386) loop of the β-subunit. Thermodynamic and kinetic analyses of the purified γMet23Lys enzyme suggested that the introduced γLys23 residue forms an ionized hydrogen bond with βGlu381 in the loop. Consistent with this interpretation, the phenotype of γMet23Lys was restored by the second mutation, βGlu381Gln. The βGlu381Lys mutation also caused deficient energy

coupling. These results suggest that the interaction between the regions around γMet23 and βGlu381, and thus the γ-subunit residue and β-subunit DELSEED loop, are involved in energy coupling.

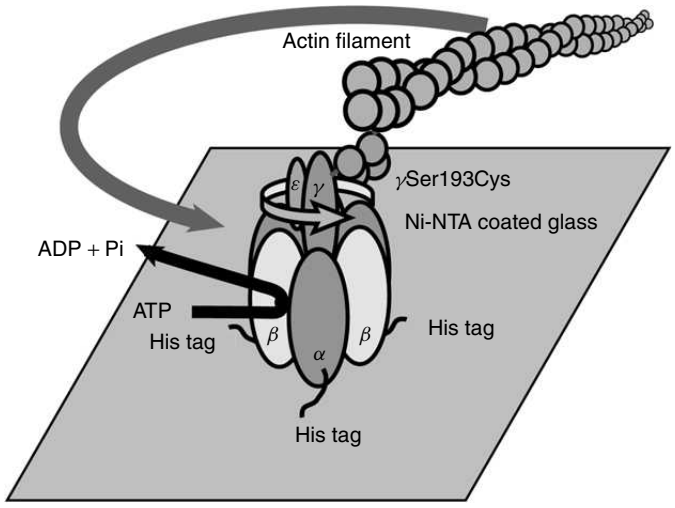
The γMet23Lys mutation was suppressed by substitution of carboxyl-terminal residues, including γArg242, γGlu269, γAla270, γIle272, γThr273, γGlu278, γIle279k, and γVal280. From these results, Nakamoto et al. suggested that γMet23, γArg242, and the region between γGlu269 and γVal280 are three interacting domains that are required for efficient energy coupling. The X-ray structure shows that γMet23 located in the amino-terminal helix is near γArg242, but γGly269 and γVal280 in the carboxyl-terminal helix are near the top of the $\alpha_3\beta_3$ hexamer. Furthermore, second-site mutations mapped to the amino (residues 18, 34, and 35) and carboxyl (residues 236, 238, 242, and 262) termini suppressed γGln269Glu and γThr273Val mutations. The higher-ordered structure clearly shows that γGlu269 or γThr273 does not interact directly with the residues of the second mutations. The occurrence of suppression at a distance may suggest that the two α-helices of the γ-subunit located at the center of the $\alpha_3\beta_3$ complex undergo long-range conformational changes during catalysis. As expected, the relative orientations of the γ-subunit to the three β-subunits (β_E, β_{DP}, and β_{TP}) are different in the crystal structure, strongly supporting γ-subunit rotation during ATP hydrolysis or synthesis.

3.2 Subunit γ-Rotation

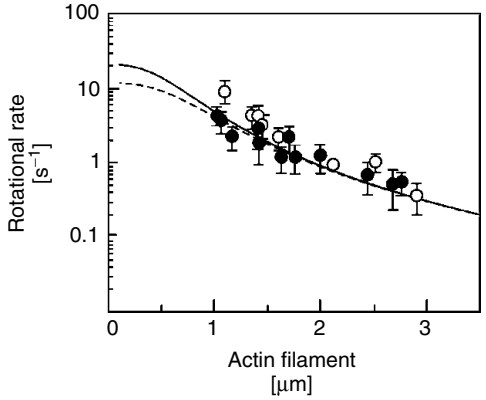
The higher-ordered structure of $\alpha_3\beta_3\gamma$ indicated that α and β are arranged alternately around the amino- and carboxyl-terminal α-helices of the γ-subunit. The binding change mechanism predicts that the catalytic sites in the three β-subunits participate sequentially in ATP synthesis or hydrolysis via conformation transmission through the γ-subunit rotation. This rotation was suggested by experiments on chemical cross-linking between γCys87 and βCys380 (originally βAsp380) in the DELSEED loop, and analysis of polarized absorption recovery after photobleaching of a probe linked to the carboxyl terminus of the chloroplast γ-subunit.

The continuous unidirectional γ-subunit rotation in F_1 was recorded directly by Noji, Yoshida, and their colleagues (Fig. 3). They immobilized the Bacillus $\alpha_3\beta_3\gamma$ complex on a glass surface through histidine residues introduced into the β-subunit. The fluorescent actin filament connected to the γ-subunit rotated continuously in an anticlockwise direction during ATP hydrolysis. The rotation became slower with an increase in the filament length, and generated a frictional torque of ~40 pN nm. The ε-subunit rotation was also shown using the same approach, consistent with the tight association of γ and ε. A 120° step rotation was shown in the presence of a dilute ATP concentration, indicating that the γ-subunit rotates, interacting with the three β-subunits successively. Furthermore, a refined measurement system involving gold beads revealed that the 120° step could be divided into 90 and 30° steps. These two steps were proposed to correspond to ATP binding and ADP release, respectively.

The rotation of an actin filament connected to the γ-subunit of *E. coli* F_1 was observed using a similar system to that described for the Bacillus $\alpha_3\beta_3\gamma$ complex. The rotation was anticlockwise, inhibited by azide (F-ATPase inhibitor),



(a)



(b)

Fig. 3 Rotation of the γ-subunit of F-ATPase. F_1 was immobilized through a histidine tag introduced to the α- or β-subunit, and an actin filament was connected to the carboxyl terminus of the γ-subunit. ATP-dependent rotation of the wild-type (open circles) and γMet23Lys mutant (filled circles) F_1 sector are shown. Taken from Omote, H., Sambonmatsu, N., Saito, K., Sambongi, Y., Iwamoto-Kihara, A., Yanagida, T., Wada, Y., Futai, M. (1999) The γ-subunit rotation and torque generation in F_1-ATPase from wild-type or uncoupled mutant Esche, *Proc. Natl. Acad. Sci. U.S.A.* **96**, 7780–7784. Experimental procedure developed by Noji et al. (1997).

and generated a frictional torque of ~40 pN·nm, as reported for the Bacillus complex. The F_1 sector, proven to be a chemically driven motor, should be connected functionally to the F_0 sector to complete ATP-driven proton transport. Conversely, proton transport through F_0 should be coupled to the γ-subunit

rotation and chemistry at the catalytic sites. Questions on the energy coupling among chemistry, rotation, and proton transport will be answered with the *E. coli* enzyme by taking advantage of the accumulated genetic and biochemical information.

3.3 Mutational Analysis of the γ-Subunit Rotation

We were interested in characterizing the γ-rotation of a series of mutant enzymes defective in energy coupling and catalytic cooperativity. As described above, the γMet23Lys mutant is defective in energy coupling between catalysis and proton transport. We thought that the γ-rotation in the mutant F_1 may be defective since the γ-residue was replaced. Similar to the original mutant, the γMe23Lys enzyme engineered for rotation observation exhibited essentially the same ATPase activity as the engineered wild type. However, the enzyme could not form an electrochemical proton gradient in membrane vesicles, or carry out *in vivo* oxidative phosphorylation. Unexpectedly, an actin filament connected to the γ-subunit of γMet23Lys rotated, and generated essentially the same torque as that of the wild type (Fig. 3). These results suggest that the γMet23Lys mutant F-ATPase could couple between chemistry and rotation, but was defective in transforming mechanical work into proton translocation or vice versa. In this regard, Al-Shawi et al. showed that the γMet23Lys mutant is defective in communication between F_1 and F_0. These results also suggested that analysis of F_1 sector rotation is not enough to understand F-ATPase catalysis. It became imperative to determine which subunit complex is rotating in the F-ATPase holo enzyme purified or embedded in the membrane.

Mutant F_1 sectors with substitution of the βSer174 residue and their suppressors have been useful for understanding the rotation mechanism (Fig. 4). Replacing βSer174 with other residues altered the ATPase activity to between 150 and 10% of the wild-type level, and the larger the side chain of the residue introduced, the lower the ATPase activity observed. Both the βSer174Leu and βSer174Phe enzymes retained about 10% of the wild-type ATPase activity. However, the two mutants showed a difference in energy coupling: the βSer174Leu mutant could still grow on succinate by oxidative phosphorylation and transport protons into the isolated membrane vesicles, whereas the βSer174Phe mutant could not grow and showed no proton transport. Consistent with these observations, their F_1 sectors differed in γ-subunit rotation. The F_1 sector with βSer174Phe showed apparently slower rotation than the wild type, and generated significantly lower frictional torque ($\sim$17 pN nm), whereas the F_1 with βSer174Leu was similar to the wild type. These results suggest that the rotation or torque generation is closely related to the energy coupling with proton transport.

Biochemical defects of the βSer174Phe mutation were suppressed by a second-site mutation, βGly149 to Ser, Cys, or Ala. Double mutants such as βSer174Phe/βGly149 Ser showed essentially the same ATPase activity and proton transport as the wild type. As expected from these results, the double mutant F_1 generated the wild-type torque ($\sim$40 pN nm). The high-resolution structure of the bovine F_1 predicts that βSer174 is located on the β-subunit surface within the loop between an α-helix (helix B) and a β-sheet (β-sheet 4) (Fig. 4). βGly149, the first residue of the phosphate-binding P-loop connected to helix B, is

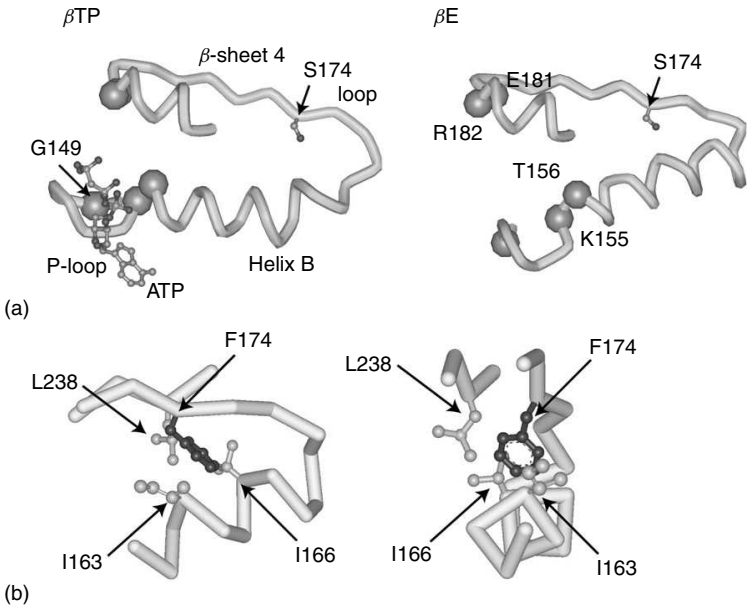


Fig. 4 Models of the *E. coli* β-subunit domain including βGly149 and βSer174. (a) Domain structure for the ATP-bound (β_{TP}) and empty (β_E)β-subunit. The bovine structure was used to model *E. coli* domains. Positions of ATP and residues discussed in the text are indicated. Nomenclatures for the α-helix and β-sheet are those of Abrahams et al. (1994). (b) Models of the βSer174Phe mutant domain structure. The positions of the residues discussed in the text are shown. Taken from Iko, Y., Sambongi, Y., Tanabe, M., Iwamoto-Kihara, A., Saito, K., Ueda, I., Wada, Y., Futai, M. (2001) ATP synthase F_1 sector rotation. Defective torque generation in the β subunit Ser-174 to Phe mutant and its suppression by second mutations, *J. Biol. Chem.* **276**, 47508–47511.

close to the catalytic site. The structure of the βGly149–βSer174 region is significantly different between the nucleotide-bound and empty β-subunits. Thus, it can be assumed that the conformational change of the catalytic site, followed by that of the βGly149–βSer174 domain, leads to the γ-subunit rotation for the energy coupling to proton transport. The βSer174Phe mutation was also suppressed by αArg296Cys of the α-subunit. It is of interest to analyze the rotation of the double mutant and related strains.

Energy minimization with a simple potential function of the modeled βSer174Phe mutant F_1 predicts that the side chain of βPhe174 interacts with that of βIle163 or βIle166 of the β-subunit with no nucleotide bound. We substituted βIle163 or βIle166 with a less bulky Ala residue in the βSer174Phe mutant. As expected, the F_1 with the βIle163Ala/βSer174Phe or βIle166Ala/βSer174Phe double mutant could rotate and generate almost similar torque to the wild type. These results suggest that the βGly149–βSer174 domain plays important roles in the rotation and torque generation essential for energy coupling.

The role of the DELSEED loop has been focused on because its conformation is significantly different among the three

β-subunits (β_E and β_T or β_D), consistent with the roles of γMet23 and βGlu381 (the second residue of the DELSEED loop) in energy coupling. However, mutagenesis studies involving replacement of residues in the DELSEED loop of thermophilic Bacillus $\alpha_3\beta_3\gamma$ did not reveal significant effects on the torque generation. The negative results may suggest that the loop is not related to the conformation change driving the β-subunit rotation. However, this is difficult to conclude from the directed mutations without structural analysis. Furthermore, the experimental system with actin filaments gives rotation rates and torque values with high deviations. Extensive substitution of related residues and their second mutations should be analyzed for the final conclusion, as discussed earlier, for a region around βSer174. Analysis of rotation in the F-ATPase holoenzyme may be necessary, as pointed out, for the γMet23Lys mutation.

4
Rotational Catalysis of the F-ATPase Holoenzyme

4.1
Structure of F_0Sector and Proton Transport Pathway

As discussed earlier, the F_0 membrane sector is composed of *a*-, *b*-, and *c*-subunits, whose stoichiometry ($1:2:10 \pm 1$, for a : b : c) was first determined from the stained bands on polyacrylamide gel electrophoresis. On the basis of structural prediction, Cox et al. proposed a model of F_0 in which the *a*- and *b*-subunit helices are surrounded by a ring of *c*-subunits. However, this model was not consistent with the electron and atomic force microscopic images. In the model derived from the images, the *a*- and *b*-subunits are attached to one side of the symmetric ring structure formed by the *c*-subunits. An atomic force microscope image indicated <12 *c*-subunits in the ring. The ab_2 complex was purified recently after solubilization of F_0 from membranes utilizing a histidine tag introduced at the *a*-subunit amino terminus. The proton pathway (F_0) was reconstituted from the ab_2 complex and *c*-subunit, confirming that ab_2 and the *c*-ring are two functional subcomplexes of the F_0 sector.

Subunit *a* spans the membrane with five helices, and its fourth helix could be cross-linked to the carboxyl-terminal helix of a *c*-subunit when Cys residues were introduced at appropriate positions, *a*Arg210 in the fourth helix is involved in proton transport, and all the substitutions, even *a*Arg210 to Lys, gave an F_0 sector with no ability to transport protons. The structure of the amino terminus (residues 1–34) of the *b*-subunit, including the transmembrane helix, was solved by NMR in a chloroform–methanol–water mixture. Extramembrane helices interact with the δ- and α-subunits at the top of the F_1 sector, which is consistent with the model proposing that the *b*-subunit closely interacts with an $\alpha_3\beta_3$ hexamer. The *b*-subunit dimer interaction with the F_1 sector is necessary for a second stalk. The carboxyl-terminal helix of a *c*-subunit can be cross-linked to the membrane helix of the *b*-subunit. Fillingame and coworkers solved the structure of the *E. coli c*-subunit by NMR: monomeric *c* (in a mixture of chloroform, methanol, and water, pH 5) gave a hairpin-like structure formed from the two helices connected by a polar region that interacts with the γ- and ε-subunits. Structural models of F_0

and the *c*-ring were reviewed recently by Fillingame and coworkers.

The front face of one *c*-subunit packs with the back face of a second *c*-subunit to form a dimer, consistent with the results of mutant studies. Fillingame and coworkers proposed that dimers form a ring of 12 monomers, with the amino and carboxyl α-helices of each *c*-subunit in the interior and at the periphery, respectively, and the ring was modeled from the results of molecular dynamic calculations. The model was supported by cross-linking analysis. However, a ring containing more than 10 monomers was not found in purified F_0F_1, and recent recalculation gave essentially the same, but a slightly smaller ring, formed from 10 copies of the *c*-subunit with the two helices in similar orientations. In an alternative model, the carboxyl- and amino-terminal α-helices form inner and outer rings, respectively. However, this model is not supported by cross-linking experiments. The X-ray structure indicated an yeast F_1 tightly bound with a *c*-ring formed from 10 monomers.

These results established that the *c*-subunits form a ring of 10 monomers. However, the number of monomers forming the ring is still controversial: atomic force microscopy of chloroplast and bacterial F_0 demonstrated rings of 14 and 11 *c*-subunits, respectively. The difference in the copy number may be due to the difference in species, loss of a part of the monomers, or reorganization of the ring during purification. Structural studies on F-ATPase or the F_0 sector will eventually explain the discrepancy.

*c*Asp61, in the middle of the second transmembrane α-helix, is responsible for proton transport, and close to *c*Ala24 and *c*Ile28, of which substitutions by other residues reduced the DCCD reactivity of *c*Asp61. The stoichiometry of the *a*- and *c*-subunits (1 : 10) indicates that one *a*Arg210 and multiple *c*Asp61 are required for proton translocation in F-ATPase. As the pK_a of the *c*Asp61 carboxyl moiety is 7.1, the NMR *c*-subunit structure at pH 5 is at the fully protonated stage. The interaction between *c*Asp61 and *a*Arg210 may lower the pK_a to facilitate proton release into the proton pathway. Rastogi and Girvin solved the *c*-subunit structure at pH 8, with *c*Asp61 being in an almost completely deprotonated form. The difference between the *c* structures at pH 5 and 8 is that the carboxyl-terminal α-helix was rotated by 140° with respect to the amino-terminal helix. From the two structures and the results of cross-linking experiments, Fillingame suggested that the carboxyl-terminal α-helix rotates during proton transport, interacts with *a*Arg210, and deprotonates *c*Asp61. This *c*-subunit structural change possibly drives stepwise rotation of the *c*-ring.

4.2 Rotational Catalysis of the F-ATPase Holoenzyme

To complete ATP hydrolysis-dependent proton transport, the γ-rotation should be transmitted to the F_0 membrane sector. Conversely, for ATP synthesis, proton transport through F_0 should generate torque to drive the γ-subunit rotation coupled to chemistry. The γ-rotation should be coupled to protonation–deprotonation of *c*Asp61 in either direction. Depending on the modeling of F_0 (*a*- and *b*-subunit inside the *c*-ring), rotation of *a*, *b*, γ, δ, and ε relative to the complex of α, β, and the *c*-ring once has been suggested. This speculation led to experimental tests, although an alternative model in which the *c*-subunit ring attached by the *a*- and

b-subunit helices is supported experimentally, as discussed above.

Different mechanisms could be proposed for the coupling between γ-rotation within the $\alpha_3\beta_3$ hexamer and proton transport through the F_0 sector: (1) the γ-subunit rotates on the surface of the *c*-ring; and (2) the γ-subunit and the *c*-ring rotate as a single complex. Models should be consistent with the proton transport continuously utilizing one *a*Arg210 and 10–14 *c*Asp61 residues of the *a*-subunit and the *c*-ring, respectively. Consistent with mechanism (2), energy transduction of F-ATPase with a counterrotating rotor ($\gamma\varepsilon c$ ring) and stator has been proposed. Convincing evidence supporting this mechanism includes the results of chemical cross-linking. Cross-linking between the γ- and *c*-subunits did not affect F-ATPase activity, indicating that sequential interaction of the rotating γ-subunits with multiple *c*-subunits is not necessary during ATP synthesis–hydrolysis. Similarly, cross-linking between the γ- and ε-subunits did not affect ATP hydrolysis, supporting the rotation of an actin filament connected to either subunit. However, $\alpha-\gamma$, $\alpha-\varepsilon$, $\beta-\gamma$, and $\beta-\varepsilon$ cross-linking resulted in loss of the activity, confirming that $\varepsilon\gamma$ rotates against $\alpha_3\beta_3$. These results suggest that a complex formed from γ-, ε-, and *c*-subunits is a mechanical unit for relative rotation to the $\alpha_3\beta_3$ hexamer.

We obtained direct evidence of continuous rotation of the *E. coli* $\varepsilon\gamma c_{10-14}$ complex during ATP hydrolysis (Fig. 5). F-ATPase engineered for rotation was solubilized from membranes, purified, and immobilized through histidine tags introduced into the α-subunit (Fig. 5a). Upon the addition of ATP, the filament connected to the *c*-ring rotated anticlockwise continuously, and generated similar torque to that observed for the γ-rotation in the F_1 sector. The rotation was inhibited by venturicidin, a specific inhibitor for F-ATPase but not for ATPase activity of the F_1 sector. The rotation and ATPase activity became less sensitive to the antibiotic when the *c*Ile38Thr mutation was introduced into the *c*-subunit, indicating that antibiotic binding to the *c*-ring inhibited rotation.

Pänke et al. also observed *c*-subunit rotation during ATP hydrolysis. They immobilized F_0F_1 through a histidine tag introduced into the β-subunit, and an actin filament was connected to the *c*-subunit through a streptag and streptavidin. The characteristics of the rotation observed were the same as those with the above systems. These results are consistent with the recent experiments showing that complete cross-linking of the γ-, ε-, and *c*-subunit had no effect on ATP hydrolysis, proton translocation, or ATP synthesis.

The important conclusion drawn from these experiments is that the *c*-subunit ring rotates when F-ATPase is immobilized through the α- or β-subunit. As discussed by Pänke et al. and Wada et al., it is not easy to prove that all the subunits were integrated into F-ATPase rotating under the microscope. However, indirect evidence supports the intactness of the enzyme used for rotation: reconstitution studies indicated that the *a*-, *b*-, and *c*-subunit are required to form F_0 capable of F_1 binding, and all F_1 subunits are required for binding to the F_0 sector. Early genetic and biochemical studies led to the conclusion that all three F_0 subunits are required for F_1 binding. The intactness of F-ATPase in these observations was also supported by the results for the membrane-bound enzyme, which rotated in essentially a similar manner to the purified F-ATPase.

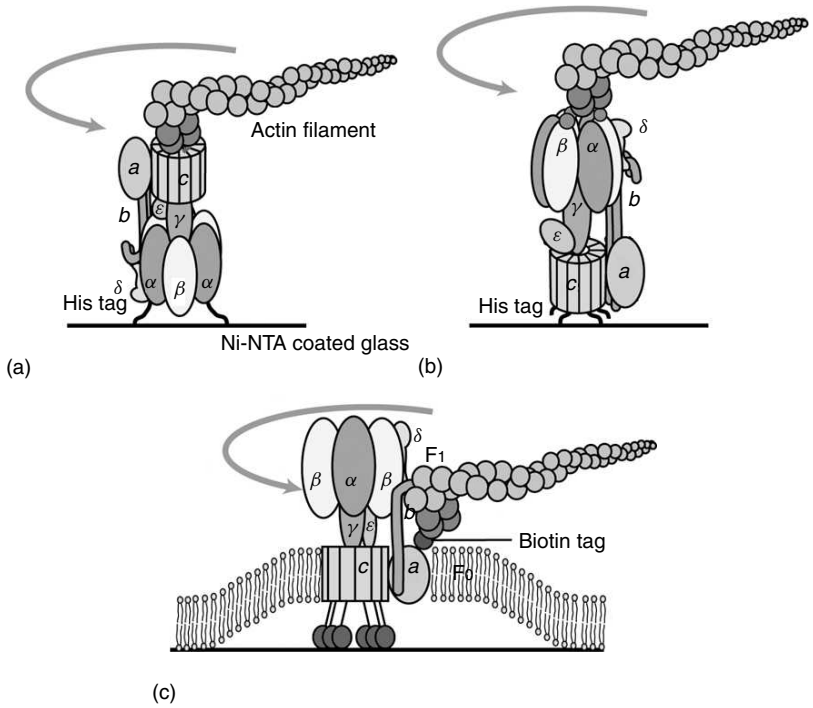

Fig. 5 Rotational catalysis of F-ATPase. F_0F_1 was immobilized through a histidine tag attached to the α-subunit (a) or *c*-ring (b, c), and a fluorescent actin filament was connected as a probe to the *c* (a), α (b), or *a* (c) subunit to observe rotational catalysis. Continuous rotation of the probe connected to the purified F_0F_1 (a or b) or membrane-embedded F_0F_1 (c) was observed upon addition of ATP.

We further addressed the basic question of whether the rotor and stator are interchangeable in F-ATPase (Fig. 5b). Thus, F-ATPase was immobilized on a glass surface through a histidine tag introduced into the *c*-subunit, and an actin filament was connected to the β-subunit through the biotin-binding domain of transcarboxylase (biotin tag). ATP-dependent filament rotation generated the same frictional torque as observed above, similar to the case of F-ATPase immobilized through the α- or β-subunit and with an actin filament connected to the *c*-subunit. Thus, either of the two subcomplexes ($\varepsilon\gamma c_{10-14}$ or $\alpha_3\beta_3\delta ab_2$) could be a rotor or a stator. Their actual roles *in vivo* will depend on the viscous drag due to the cytosol and membranes.

4.3 Rotational Catalysis of F-ATPase in Membranes

Although rotation of the $\gamma\varepsilon C_{10-14}$ complex has been shown using purified F-ATPase, a more favorable experimental system is the isolated membrane because the original integrity of the enzyme is maintained. The membrane could be used to answer one of the obvious questions of whether the *c*-ring rotates relative to the *a*-subunit. Such rotation would support the model of proton transport through the interface of the two subunits (Fig. 5c). It may be difficult to

test the rotation of a probe connected to the *c*-ring embedded in membranes by immobilizing F-ATPase through the α- or β-subunit. As described earlier, purified F-ATPase can be immobilized through a histidine tag connected to the *c*-ring, and an actin filament can be connected to the α- or β-subunit through a biotin tag. This experimental system was modified to test the rotation of F-ATPase in the membrane. As histidine and biotin tags face the periplasm and cytoplasm of the intact *E. coli* cell, respectively, membrane preparation for rotation should be carefully considered. Right-side out or everted membrane vesicles cannot be used for testing rotation, because only one of the two tags in these vesicles is accessible from the medium: the histidine tag faces the medium for right-side out vesicles, but the biotin tag is inside the same vesicles. Similarly, the histidine tag is inside everted vesicles, and thus cannot be used for immobilizing F-ATPase in these vesicles. Therefore, F-ATPase in planar membranes should be used to test for the rotation.

We prepared membrane fragments by passing *E. coli* cells through a French press by a slight modification of the procedure used to prepare everted vesicles. A labeling experiment with streptavidine-conjugated gold particles indicated that the preparation contained a significant number of planar membranes. Using this preparation, we observed ATP-dependent rotation of an actin filament connected to the β-subunit. As expected from the previous studies, the rotation was counterclockwise and sensitive to DCCD.

To complete a model of proton translocation through the rotation in F-ATPase, it is essential to show rotation of the *c*-ring relative to the *a*-subunit (Fig. 5c). The *c*-subunit (*c*Met65Cys) cross-linked with the *a*-subunit (αAsn214Cys) was highly protected from labeling with ^{14}C-DCCD. However, when F-ATPase was labeled with ^{14}C-DCCD and subjected to the ATPase reaction before cross-linking, there was significantly increased labeling of the $a-c$ dimer. This experiment supports the rotational catalysis in F_0, although no

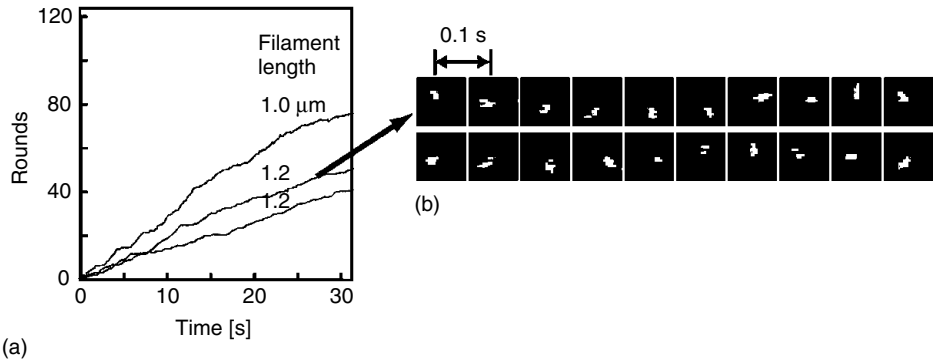

Fig. 6 Relative rotation of the *a*-subunit in membrane-embedded F-ATPase. Time courses of rotating filaments connected to the *a*-subunit of membrane F-ATPase immobilized through the *c*-subunit are shown, along with time courses of rotating filaments of varying length (a) and typical sequential video images (video interval, 100 ms) (b). Taken from Nishio, K., Iwamoto-Kihara, A., Yamamoto, A., Wada, Y., Futai, M. (2002) Subunit rotation of ATP synthase embedded in membranes: a or βsubunit rotation relative to the *c* subunit ring, *Proc. Natl. Acad. Sci. U.S.A.* **99**, 13448–13452.

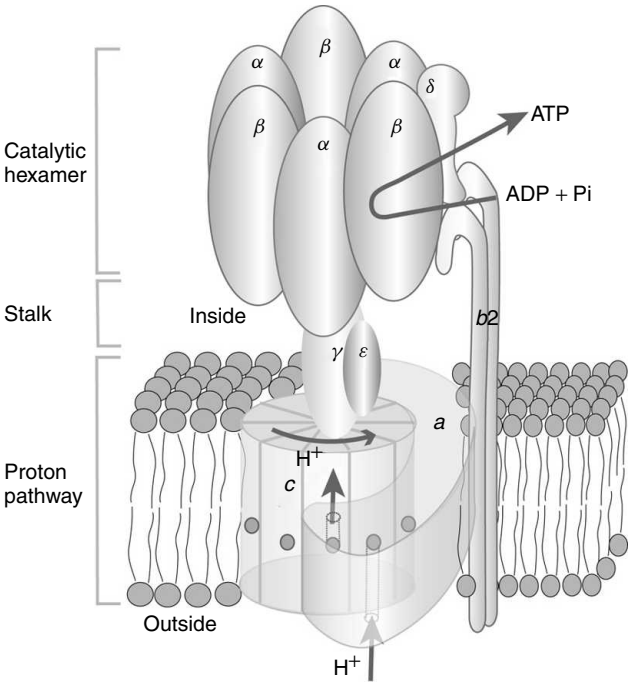

Fig. 7 Schematic mechanism of rotational catalysis by F-ATPase. For ATP synthesis, electrochemical proton transport changes the *c*-subunit conformation that drives the rotational movement of the *c*-ring together with the γ- and ε-subunits. Conversely, ATP hydrolysis drives the γ- and ε-subunit rotation together with the *c*−ring to transport protons. Modified from Wang, H., Oster, G. (1998) Energy transduction in the F_1 motor of ATP synthase, *Nature* **396**, 279–282; Fillingame, R.H., Angevine, C.M., Dmitriev. O.Y. (2002) Coupling proton movement to *c*-ring rotation in F_0F_1 ATP synthase: aqueous access channel and helix rotations at a–c interface, *Biochim. Biophys. Acta* **1555**, 29–36; Junge, W., Lill, H., Engelbrecht, S. (1997) ATP synthase: an electrochemical transducer with rotatory mechanics, *Trends Biochem. Sci.* **22**, 420–423.

information on the mechanism could be obtained. We could show rotation of the actin filament connected to the *a*-subunit relative to the *c*-ring using membrane fragments (Fig. 6).

These results and those obtained with purified F_0F_1 or the F_1 sector indicate that $\gamma\varepsilon c_{10-14}$ and $\alpha_3\beta_3\delta ab_2$ are mechanical units, that is, an interchangeable rotor and stator, respectively. Notably, the results obtained with membrane-embedded F-ATPase and those with the purified one are similar. Furthermore, the experimental system will be extremely valuable for studying the mechanism of coupling of rotation and proton transport, although further modification(s) may be necessary.

These studies established rotational catalysis by F-ATPase (Fig. 7). For ATP hydrolysis, the F-ATPase is a chemically driven motor rotating $\gamma\varepsilon c_{10-14}$ to drive proton transport. Studies on the

mechanism of the rotation in the F_0 sector were started only recently. The rotation is inhibited by venturicidin or DCCD, suggesting that the tight or covalent binding of these bulky chemicals to the *c*-subunit inhibits mechanical rotation. Junge and coworkers showed that the *c*-subunit ring with the *c*Asp61Asn mutation can still rotate during ATP hydrolysis, indicating that the proton transport is not obligatory for the chemically driven rotation (ATP hydrolysis-dependent *c*-ring rotation). For ATP synthesis, the same enzyme is a potential-driven motor rotating $\gamma\varepsilon c_{10-14}$ through an electrochemical proton gradient. This membrane system will be useful for studying the rotation in this direction.

5
Rotational Catalysis of V-ATPASE

5.1
Catalytic Site and Proton Pathway

V-ATPase (vacuolar-type ATPase) acidifies the lumens of endomembrane organelles such as lysosomes, endosomes, and synaptic vesicles. The same enzyme in the plasma membranes of specialized cells, including osteoclasts and renal intercalated cells, pumps protons into extracellular compartments such as resorption lacunae and collecting ducts, respectively. Despite significant physiological differences, V-ATPase exhibits similarities with F-ATPase. The catalytic *A*-subunit of V-ATPase is homologous to F-ATPase β. The homology is striking in the phosphate-binding P-loop and other sequences, including the F-ATPase catalytic residues discussed above. *E. coli* F-ATPase residues at the catalytic site, βLys155, βThr156, βGlu181, βArg182, and βGlu185, correspond to *A*Lys263, *A*Thr264, *A*Glu266, *A*Arg267, and *A*Glu290 of the yeast V-ATPase *A*-subunit, respectively (Fig. 2). Mutational studies of yeast V-ATPase supported the notion that they are catalytic residues. The kinetics indicate that V-ATPase has three catalytic sites exhibiting cooperativity. The cysteine residue in the V-ATPase P-loop may be involved in regulation. F-ATPase with Cys introduced at the corresponding position became sensitive to sulfhydryl reagents, similar to V-ATPase.

The membrane V_0 sector of V-ATPase has a more complicated subunit composition: yeast V_0 is formed from *c*-, *c*′-, *c*″-, *a*-, and *d*-subunits. Of the three proteolipid subunits, the *c*- and *c*′- having four transmembrane helices are a duplicated form of the F-ATPase *c*-subunit, and show 56% identity in amino acid residues with each other. The carboxyl moieties (*c*Glu137 and *c*′Glu145) for proton transport are located on the fourth helix of the *c*- and *c*′-subunits, respectively. The *c*″-subunit, exhibiting some homology with *c* and *c*′, is also required in proton transport: *c*″Glu188 in the middle of the third α-helix is also implicated for proton transport. The *c*″-subunit is conserved in mammalians, whereas the *c*′-subunit is only found in yeast. The stoichiometry of the $c : c' : c''$ subunits in yeast is n:1 : 1. The three proteolipids may form a ring structure similar to the F_0c-ring. Assuming that 4, 1, and 1 molecules of the *c*, *c*′ and *c*″ subunits, respectively, form a ring, V_0 has ~6 proton–translocating residues altogether. This is in contrast with 10–14 residues for F_0. Mutation of V-ATPase *a*Arg735 abolished proton translocation similar to that of F-ATPase *a*Arg210, although the subunit *a* of V_0 and F_0 exhibit little homology. Thus, V_0 has multiple carboxyl moieties and one arginine essential for proton translocation.

The similarities between the two ATPases raised the interesting question of whether V-ATPase can synthesize ATP. Unlike F-ATPase localized with the respiratory chain in the mitochondrial membrane, mammalian or yeast membranes containing V-ATPase do not have a system for generating an electrochemical proton gradient. Does V-ATPase synthesize ATP when a membrane potential or proton gradient is generated? To answer this question, we expressed a plant proton–translocating pyrophosphatase in yeast vacuoles. Upon hydrolysis of pyrophosphate, the vacuolar membrane vesicles could form an electrochemical proton gradient, which was lowered by the addition of ADP + Pi. As expected from this result, we observed ATP synthesis sensitive to the V-ATPase specific inhibitor bafilomycin. The results further support the similarities between the two ATPases. Plant vacuoles having both V-ATPase and pyrophosphatase may synthesize ATP similar to the yeast chimeric system.

5.2 Subunit Rotation of V-ATPase During Catalysis

Despite the similarities of V- and F-ATPase discussed earlier, they are also significantly different. Typically, F-ATPase of *E. coli* has eight subunits, whereas yeast V-ATPase has 13. Most of the subunits unique to V-ATPase are located in the stalk region. Furthermore, the presence of isoforms of subunits *B*, *E*, *G*, *d*, and *a* has been found for V-ATPase, whereas the information on isoforms is limited for F-ATPase. As pointed out above, V_0, possibly its ring structure, may be different from F_0. These differences and similarities led us to examine the rotational catalysis in V-ATPase.

As described above, rotation of an actin filament connected to the *a*-, α-, or β-subunit was observed when F-ATPase was immobilized through the *c*-subunit ring. The correspondence of minor subunits in the stalk region between the two ATPases was difficult to determine (Fig. 8).

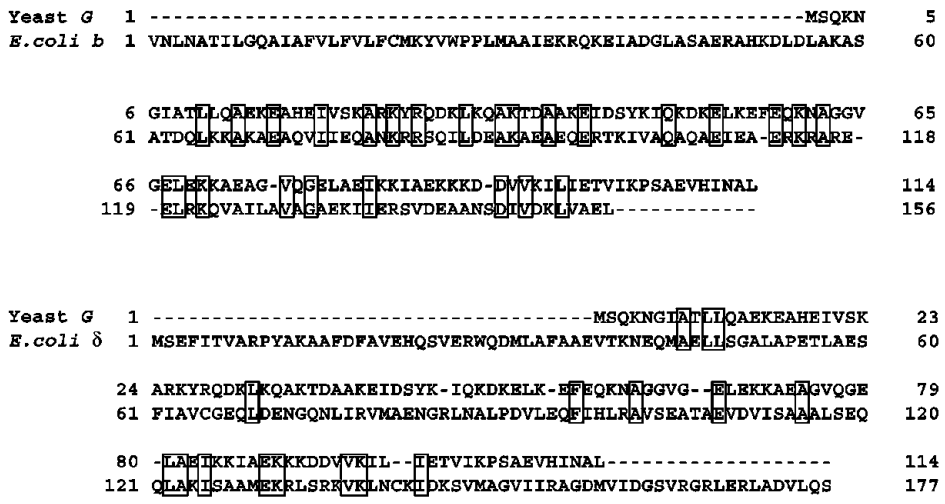

Fig. 8 Similarities of the V-ATPase *G*-subunit with the F-ATPase *b*- or δ-subunit. The subunits are aligned to obtain maximal homology. Identical amino acid residues are boxed.

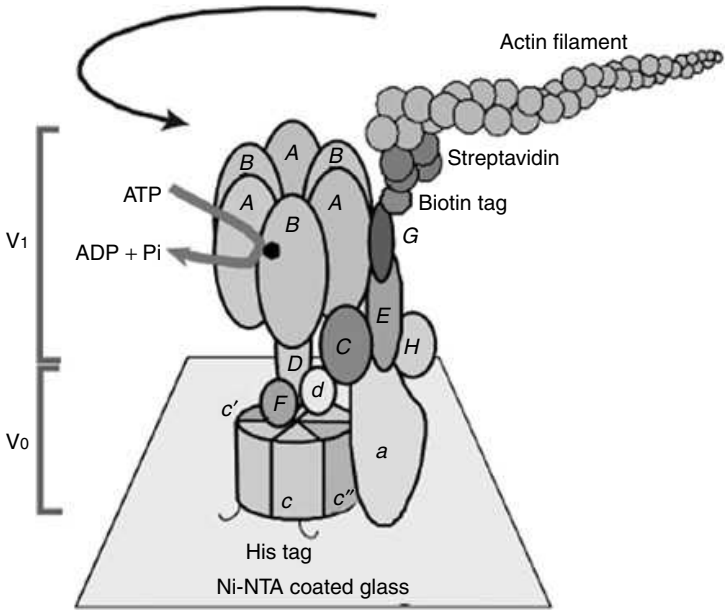

Fig. 9 Rotation of an actin filament connected to the *G*-subunit of V-ATPase. Solubilized V-ATPase was immobilized on a glass surface through the *c*-subunit, and an actin filament was connected to the *G*-subunit. Rotation was observed upon the addition of ATP, and inhibited by nitrate and concanamycin. Taken from Hirata, T., Iwamoto-Kihara, A., Sun-Wada, G.-H., Okajima, T., Wada, Y., Futai, M. (2003) Subunit rotation of vacuolar-type proton pumping ATPase: relative rotation of the G and C subunits, *J. Biol. Chem.* **278**, 23741–23719.

The *G*-subunit was suggested to exist in the stalk domain of a recent model, and to be accessible from the cytosol. The *G*-subunit and F-ATPase *b* exhibit ~24% homology, although the *G*-subunit lacks a transmembrane region. However, recent cross-linking studies suggested that the *G*-subunit is located near the top of V_1, similar to the F-ATPase δ-subunit. Thus, the *G*-subunit may correspond to the *b* or δ-subunit of F_1, and could be a candidate for connecting a probe to observe rotation, although the homology is quite limited.

On the basis of these considerations, we engineered the yeast chromosome (*VMA3* and *VMA10* for the *c*- and *G*-subunit, respectively), solubilized V-ATPase from vacuolar membranes, and tested rotational catalysis. An actin filament connected to the *G*-subunit rotated upon ATP hydrolysis (Fig. 9). The rotation was inhibited by nitrate and concanamycin, similar to their effects on ATPase activity. Concanamycin inhibition was striking: the rotation terminated within a few seconds after the addition, which is consistent with its tight affinity. This antibiotic is similar to bafilomycin, which binds to the V_0 sector, possibly to its *c*-subunit, indicating that concanamycin, possibly bound to the rotor–stator interface, terminated the rotation. Torque generated by the rotation was similar to that with F-ATPase.

These results suggest that the A_3B_3 hexamer rotates together with the *G*-subunit when the *c*-subunit ring is immobilized. An interesting question is ''Which part of the V-ATPase rotates *in vivo*?'' In this regard, Holiday and coworkers reported that the *B*-subunit interacts with the cytoskeleton, possibly actin. Thus, the *c*-subunit ring together with the subunit corresponding to the γ- (possibly D) subunit may be rotating *in vivo* if the V-ATPase holo enzyme is immobilized with the cytoskeleton. However, it is also possible that the rotor–stator is determined only by the slight difference in viscous drag applied to each subcomplex.

The rotational catalysis of the peripheral membrane sector of *Thermus thermophilus* ATPase was shown recently. This Archaean ATPase is more similar to F-ATPase than V-ATPase, as pointed out by the authors. In this regard, the ATPase of Archae (Archaean bacterial) plasma membranes has been classified as an A-type ATPase. Thus, three related proton–translocating ATPases carry out common rotational catalysis.

6 Epilogue

Proton-translocating F-ATPase (ATP synthase) has been a fascinating membrane enzyme for generations of biochemists. As Paul Boyer called it *A splendid molecular machine* it is more than an ordinary enzyme. F-ATPase synthesizes or hydrolyzes ATP coupling between proton translocation and chemistry, and has become a real molecular machine in this sense, since mechanical rotation of its subunit complex was included recently in its mechanism. For the engineering aspect of the mechanism, the F_1 sector immobilized on a metal surface can rotate a metal plate.

As described above, experimental systems have been established for further studies. Details of the rotation mechanism will be revealed by studies involving *E. coli* F-ATPase together with the progress regarding physical methods and the higher-ordered X-ray structure determinations of the F_0 sector.

It was interesting to learn that rotational catalysis has been expanded to V-ATPase and also distantly related Archaean ATPase. The basic mechanism of V-ATPase rotation may be similar to that of F-ATPase, as expected from the structural similarities between the two enzymes. Thus, the rotational mechanism of *E. coli* F-ATPase should be studied extensively, using its genetic and biochemical advantages. V-ATPase may have a more fascinating regulatory mechanism that is supported by a unique V_0 structure and a series of isoforms in the stalk region. The regulatory role of stalk subunit(s) including subunit *E* in energy coupling has already been discussed.

Keywords

Conserved Order
Demonstration that three or more homologous genes lie on one chromosome in the same order in two separate species.

Conserved Segment
The syntenic association of two or more homologous genes in two separate species that are contiguous (not interrupted by different chromosome segments) in both species.

Conserved Synteny
The linked association of two or more homologous genes in two separate species regardless of gene order or interspersion of noncontiguous segments between two markers.

Karyotype
The chromosome complement of an organism.

Synteny
This term simply means linkage, that is, if two genes are syntenic, they are both present on the same chromosome.

Takifugu
While this is a species of pufferfish, this is generally the abbreviated name used in this text for *Takifugu rubripes*. This species is also known as *Fugu*, *Fugu rubripes*, and *Torafugu*. Its common name is the Japanese pufferfish.

Tetraodon
While this is also a species of pufferfish, this is generally the abbreviated name used in this text for *Tetraodon nigroviridis*. In the past, this species had been misnamed as *Tetraodon fluviatilis*, which is a different species of the *Tetraodon* family. *T. nigroviridis* is currently designated as *Chelonodon nigroviridis* in Fishbase. Its common name is the spotted green pufferfish.

The pufferfish have some of the smallest vertebrate genomes known (350–500 Mb). This lead to two species, the Japanese pufferfish and the spotted green pufferfish (*Takifugu rubripes* and *Tetraodon nigroviridis* respectively), being adopted as model vertebrates for in-depth genome-sequencing programs. These data have provided a wealth of information for comparative genomics studies in both fish and other vertebrate species, particularly human. This article describes the generalized features of the pufferfish genomes, the genome projects and resources available, in addition to the development of the pufferfish as genome tools.

1 Introduction

The raison d'être behind the pufferfish genome projects has to be viewed in a historical context. When the initial pufferfish genome project (using *Takifugu*) was proposed by Sydney Brenner in the early 1980s, sequencing technologies were still in their infancy. The sequencing programs of *Escherichia coli* and *Caenorhabditis elegans* had been started and it was these that provided the impetus behind the development of the high-throughput technologies, which are taken for granted today. Having said that, it did not seem conceivable at that time that they could be improved to such an extent as to allow the sequencing of the human genome. Therefore, Sydney Brenner proposed the need for an economical vertebrate model genome to bridge the gap between the data arising from the bacterial and invertebrate projects and human (Table 1). It had been known since 1968, from the work of Hinegardner, that several species of pufferfish had small genomes of approximately 0.4 pg per haploid nucleus (400 Mb). This equates to approximately one-eighth the size of the human genome. After preliminary sequencing scanning experiments showed a similar gene content to human, *T. rubripes* became accepted as a universal model genome. However, *Takifugu* was in some ways rather limited; it was only available from Japan and was therefore not universally accessible to researchers; it also grows rapidly to 1 kg within the first year and so cannot be kept in small laboratory fish tanks. Therefore, an alternative pufferfish species was proposed by Hans Lehrach – the spotted green pufferfish or *T. nigroviridis*. This is a

Tab. 1 Genome sizes of selected organisms. When the pufferfish was proposed as a model genome, sequencing technologies were relatively limited, with work started only on the bacteria and *Saccharomyces cerevisiae* and *C. elegans*.

Organism	*Common name*	*Genome size [Mb]*
Escherichia coli	Bacteria	4.64
Saccharomyces cerevisiae	Yeast	14
Caenorhabditis elegans	nematode	97

Rattus norvegicus	rat	3000
Mus musculus	mouse	2500
Homo sapien	human	3000

small freshwater pufferfish that is available from many aquarium shops worldwide and so can be easily kept in most laboratories, providing a readily available source of DNA and tissue-specific RNA. Paradoxically, with the massive improvement in sequencing technologies, the human genome has been sequenced in advance of the pufferfish and the excess capacity of the large sequencing factories has since enabled the sequencing of both pufferfish genomes. The data from these is proving extremely valuable in comparative genomics and in the functional characterization of genes, as will be discussed Sect. 5.

2 Classification, Habitat, and Morphology of Pufferfish

2.1 Classification and Geographical Distribution of Pufferfish

Both pufferfish species (*T. rubripes* and *T. nigroviridis*) are members of the series Percomorpha, order Tetraodontiformes, family Tetraodontidae. The Tetraodontidae family comprises 19 genera with approximately 121 species. They are largely marine species, with several of them entering and occurring in brackish and freshwater. They live in tropical and subtropical regions, in the Atlantic, Indian, and Pacific oceans. Approximately 12 species of *Cariotetraodon, Chonerhinos*, and *Tetraodon* occur only in freshwater, primarily in the Congo river and southern Asia. The geographical locations of the two pufferfish species subject to genome sequencing are detailed further:

T. rubripes is found in the Northwest Pacific: western part of the Sea of Japan and the East China and Yellow Seas northward to Muroran, Hokkaido, Japan. It is a temperate marine species, which occasionally enters brackish waters. It grows rapidly to a large size (70 cm is thought to be the maximum size it attains) and is not thought to breed until three-years old. It is a very important commercial species in the Japanese fisheries/aquaculture industry.

T. nigroviridis is found in Asia: Sri Lanka to Indonesia, Malaysia, and north to China. It is a tropical (24–28 °C) freshwater species. It is a relatively small pufferfish species (maximum size 14 cm) and is sold in the aquarium trade worldwide.

The family Tetraodontidae is further split into two subfamilies: the Canthigastrinae (sharpnose puffers), which only comprises one genus and 26 species, while the rest are consigned to the Tetraodontinae. Paleontological evidence indicates that the families of the Tetraodontiform fishes diverged from each other between 90 and 50 million years ago, the fossil records for the Tetraodontiformes going back at least to the early Eocene (58 million years ago), indicating a long evolutionary history. Phylogenetic trees built from mitochondrial and nuclear genes showed that *Tetraodon* and *Takifugu* shared a common ancestor between 18 and 30 million years ago.

With two pufferfish genomes available for data mining, biologists are increasingly interested in related species as a means of exploiting these as biological models. While the order Tetraodontiformes is well defined (Fig. 1), there is relatively little information on the relationships between the different family members.

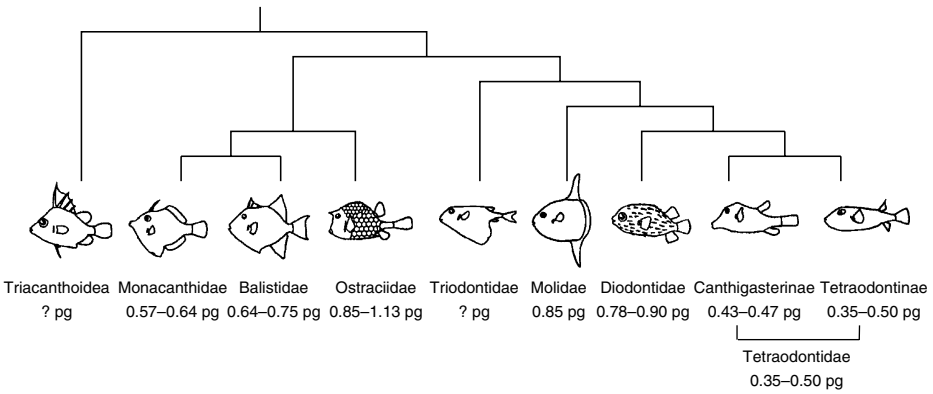

Fig. 1 Phylogeny and haploid genome sizes for sampled members of seven Tetraodontiform families. The phylogeny was based on morphological characters by Winterbottom, 1974. Figure reproduced from Brainerd, E.L., Slutz, S.S., Hall, E.K., Phillis, R.W. (2001) Patterns of genome size evolution in tetraodontiform fishes, *Evolution Int. J. Org. Evolution* **55**, 2363–2368, with permission.

2.2 Pufferfish Morphology

Pufferfish are generally recognized as the most advanced order of the teleosts, having a highly derived body form. The name Tetraodontiformes literally means four-toothed, which refers to the common pattern of four teeth in the outer jaws, although it has to be said that, on first glance, these often resemble more of a beak structure. Pufferfish are characterized by a high degree of fusion or loss of numerous bones in both the head and body. They usually have no lower ribs and have a reduced number of vertebrae when compared to most other fish species. The scales are usually modified as spines, shields, or bony plates over a thick leathery skin. The pufferfish have modified stomachs, which allows them to inflate to an enormous size by gulping down water, or in some cases air, when annoyed or threatened.

Some species, including *T. rubripes*, contain the alkaloid poison tetraodotoxin in certain tissues of their body. This is one of the most potent poisons known and acts by selectively blocking the voltage-sensitive sodium channels, which are essential components in cellular signaling pathways. The pufferfish have a point mutation in the protein sequence of the sodium-channel pump and so are resistant to the poison. In *Takifugu*, tetraodotoxin is present in high concentrations in the liver and ovaries and at lower concentrations in the intestines. The flesh, skin, and testes are not poisonous. However, despite the presence of a potentially lethal poison in certain tissues, *Takifugu* is highly prized item on the sushi menu. Hence the need for specially trained chefs to prepare *Takifugu*, ensuring that none of the toxic tissues is included in the sushi.

3 Pufferfish Genomes

3.1 Genome Size

The two pufferfish have similar genome characteristics, which will be described

in general terms here. Measurements of the nuclear DNA content showed that both contain approximately 0.35 to 0.4 pg per haploid genome, equivalent to a genome size between 350 and 400 megabases (Mb). The alignment of syntenic regions between *Tetraodon* and *Takifugu* indicates that the latter is larger by approximately 10%, although it will be necessary to wait until both genome sequences are complete for a final estimate. Both genomes are equivalent to approximately one-eighth the size of the human genome.

These compact genomes are characterized by smaller intergenic regions and introns and fewer repeat sequences (less than 10% of the genome). Data from the *Takifugu* genome shows that 75% of the introns are less than 425 bp, with a modal value of 79 bp. Only 500 introns are greater than 10 kb. The comparable figures for human are a modal value of 87 bp, which is not significantly different, but the 75% threshold is raised to 2609 bp, and over 12 000 introns are greater than 10 kb. The pufferfish genomes are prized by molecular biologists for their small genes, and, in general, pufferfish genes are scaled down compared to their human orthologs; however, a note of warning: a significant number are 1.3× larger.

Questions always arise as to why the genomes are so small and about the mechanisms involved. There is great diversity in fish genome sizes and this is also true of the Tetraodontiformes. Members of the Diodontidae (the spiny pufferfish), the sister family to the Tetraodontidae (smooth pufferfish), have genomes twice as large (Fig. 1). Studies indicate that the Diodontidae genomes have reached equilibrium, that is, are stable, but that this state of equilibrium was disturbed in the smooth pufferfish, following their divergence from the spiny puffers. The smaller genomes are thought to be the result of a decline in the rate of large-scale insertions, probably as a result of decreased transposable element activity. These are often found in the genome as middle repeat sequences (approximately 20% of the *Diodon hystrix* genome), but these are rare in *Takifugu*, a conclusion that presumably extends to the other smooth pufferfish with their compact genomes.

3.2 Repetitive Elements

Aside from a reduced number of middle repeat transposable elements, other types of such elements are also present in much lower quantities (approximately 1% of the total genome) compared to the other larger vertebrate genomes. It is the number rather than the types of transposable elements that are reduced as pufferfish contain sequences homologous to all known families of transposable elements including Ty3-gypsy, Tyl-copia, LINES, DNA transposons, and retroviruses. In general, these elements are dispersed throughout the genome but not in an even manner. *In situ* localization studies in *Tetraodon* show that they are compartmentalized in specific regions that correspond to the short arms of 10 pairs of small subtelocentric chromosomes (Fig. 2). These chromosome arms are heterochromatic and also contain a large number of pseudogenes that have arisen through duplication and retrotransposition. Characterization of such genes (iSET and Trapeze) has been carried out in *Tetraodon*, but it is not known whether they are present in *Takifugu* as the heterochromatic regions have been left out of the genome assembly to facilitate contiguation.

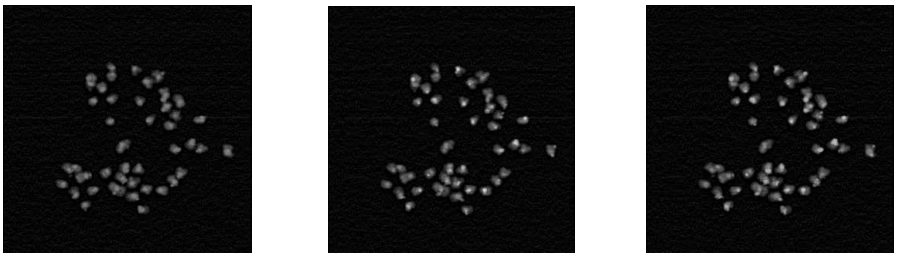

Fig. 2 *In situ* hybridization of two different non-LTR retrotransposons to *Tetraodon* chromosomes. (a) Green signals of Zebulon retrotransposon; (b)red signals of Barbar retrotransposon; (c) combined signal (yellow) of both retrotransposons. Both of these elements share the same sites in the genome, at the tip of some subtelocentric chromosomes. Babar is more abundant (in the shotgun data) and has more signals here, as seen by the additional red hybridizations in the combined data. (See color plate p. xxvii).

In addition to these transposable elements, the pufferfish genomes also contain two satellite sequences. The first is a 118-bp repeat, which maps to the centromeres. Interestingly, and despite their exact same size in both species, the two centromeric repeats show no noticeable sequence similarity. The second satellite is a subtelocentric repeat (10-mer in the case of *Tetraodon* (GGCGTCTGAG) and 20-mer in the case of *Takifugu* (GGCATCTGATCCTGGTAGCT)). Minisatellites are present to the extent of approximately 41% in *Tetraodon* (unknown in *Takifugu*) and microsatellites comprise between 2 to 3.5% of the pufferfish genomes. In total, repeat sequences comprise less than 10% of the genome.

The G + C content is higher in the pufferfish (46.2% in *Tetraodon* and 47.7% in *Takifugu*) compared to human (40.3%), which is thought to be due to the relative increased coding content. In *Takifugu*, the G + C heterogeneity is also less marked compared to mammals but is similar in *Tetraodon,* albeit shifted to higher G + C percentage. The reasons why *Tetraodon* contains more regions higher in G + C content than the closely related *Takifugu* are still unknown. In fact, a more homogeneous distribution in *Tetraodon* would be expected since it is a general condition associated with poikilothermic animals. The heterogeneous distribution of G + C content in mammals is associated with gene-rich and gene-poor regions, and the pufferfish also have gene-dense and gene-sparse regions. Overall, the average gene density in the pufferfish is one gene for every 10 kb, compared to 40 kb in human.

3.3 Gene Number

As regards the actual number of genes present in the pufferfish, there are only current estimates based on gene prediction programs. The number of predicted genes is greater than that of human (35 180 compared to 24 847), but it is suspected that fish have more genes than mammals owing- to additional duplication events. This is supported by results from whole-genome comparisons between *Takifugu* and *Tetraodon* on the one hand, and human and mouse on the other hand, which

show that the two fish contain a slight excess of regions conserved during evolution between tetrapods and teleosts. However, the number of transcripts does not seem to vary much between the two species (38 510 and 37 347). It should be noted that no estimate has been made of the rate of alternative transcription in the pufferfish and this could dramatically alter the number of transcripts. In human, 60% of genes are thought to be alternatively transcribed.

When the *Takifugu* draft genome was compared to the human sequence, three-quarters of human predicted genes showed a strong match on BLAST sequence similarity searching. One-quarter of human predicted proteins did not show a match and, therefore, are either highly diverged or not present. Six thousand *Takifugu* predicted genes showed no match to human predicted proteins. Although some of these genes may be fish-specific, it is unlikely that this is the case for the majority. Of the nonmatching human proteins, there were many cell surface receptor–ligand system proteins of the immune system, hemopoietic system, and energy/metabolism of homotherms. Immune cytokines, in general, were either not detected in *Takifugu* or showed very distant similarity. However, a focused effort to identify the class I and II cytokine receptors and their ligands in *Tetraodon* showed that the complete repertoire of these genes was present. This work required a careful examination of gene-structure conservation and a systematic cloning of transcripts for these genes, and highlights the fact that automatic annotation of genomes may leave out complete functional families, especially those submitted to accelerated sequence divergence.

3.4 Pufferfish Chromosomes

In depth, karyotypic analysis of most pufferfish chromosomes is difficult because of their small size (2 µm, on average). Therefore, most analysis is in the form of a basic giesma-stained karyotype. Cytogenetic information is available for 53 out of the 339 marine Tetraodontiformes. The Triacanthidae are considered the most basal clade of the Tetraodontiformes (based on morphological and osteologic criteria) and have a diploid chromosome complement of $2n = 2x = 48$. This mirrors the generalized Percomorpha complement from which they were derived and also represents the karyotypic base for all Tetraodontiformes (Fig. 3). Karyotypes of the more specialized species range from $2n = 2x = 28$ to 52, which are thought to represent derivations of this karyotype. This inference is supported by the occurrence of bi-armed chromosomes in this group, which is considered a derived condition in fish karyotypes.

Takifugu rubripes. $2n = 2x = 44$. Analysis of six different *Takifugu* species karyotypes shows that they are virtually identical, and the occurrence of natural hybrid species suggests that their morphology is indeed very similar. There is a large pair of submetacentric chromosomes within the complement, which is the characteristic marker chromosome pair of the group.

Tetraodon nigroviridis. $2n = 2x = 42$. In addition to the larger submetacentric chromosome pair, characteristic of the *Takifugu* species, *Tetraodon* also contains a large

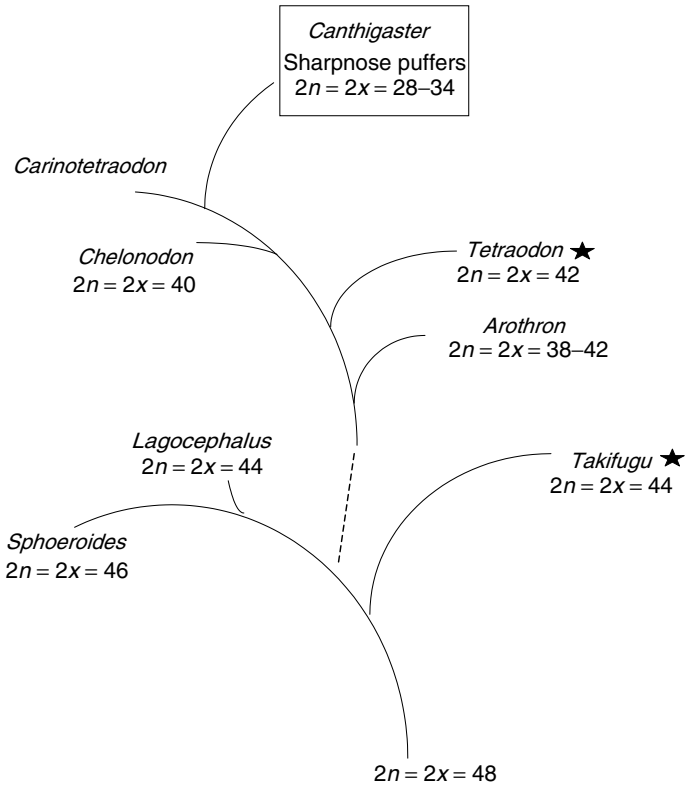

Fig. 3 Chromosome numbers of sampled Tetraodontinae overlaid on a restricted phylogeny on the basis of anatomical diversity, derived from J.C. (1980) *Osteology, phylogeny and higher classification of the fishes of the order Plectognathi (Tetraodontiformes)*. NOAA Technical Report NMFS Circular 434. US Department of Commerce, Washington, USA. Not all species of Tetraodontidae are shown. *Sphoeroides* is regarded as the most basal, having the most generalized osteology. $2n = 2x = 48$ is regarded as the ancestral karyotype. The stars indicate the species to which the sequenced pufferfish genomes belong. Virtually nothing is known about the evolutionary timescales between species in this family, although it has been estimated that *Takifugu* and *Tetraodon* diverged approximately 18 to 30 million years ago.

metacentric chromosome, presumably the result of a centric fusion between two of the smaller acrocentric chromosome pairs. This species is by far the best studied, in cytogenetic and physical mapping terms. Silver staining shows that there are two pairs of nucleolar organizer (NOR) chromosomes that are transcriptionally active.

3.5 Pufferfish Genetics

Owing to the problems in breeding these species, there are no linkage maps for pufferfish. In fact, no morphological characters enable the distinction between males and females in *Tetraodon*. Evidence

suggests that the inability to breed pufferfish may be due to some form of captive-induced stress. Histological studies of gonads have been performed in *Tetraodon* and show that both females and males are sexually mature when imported from Southeast Asia to Europe, but a high level of occlusions in female in vitellogenesis suggest that the last stages of sexual maturation are blocked because of some external factors that may be due to the stress of transportation. Breeding problems also arise with *Takifugu*, even when attempted in their native Japan, without being subjected to lengthy air-freight transportation.

4 The Genome Projects

4.1 Sequencing Projects

Both pufferfish genome projects have been generated using a Whole-Genome Shotgun (WGS) approach, where single read sequences are generated from the ends of cloned genomic DNA fragments. Both are currently at the stage of a ''working draft,'' which means that, several times, genome coverage of clones have been assembled into a series of contigs (termed *scaffolds*). These vary dramatically in size from several 100 kb to 1 to 2 kb and are gradually being assembled into increasingly larger contigs. If both pufferfish were to be completely sequenced, then there would eventually be 21 contigs for *Tetraodon* ($2n = 2x = 42$) and 22 contigs for *Takifugu* ($2n = 2x = 44$), with each contig representing one of each chromosome pair. However, it is not known whether this will be the case; some regions, such as the telomeres and centromeres, are particularly difficult to assemble, and it is more likely that each genome will remain as a draft. Because of the nature of these projects, data are continually changing and, therefore, specific details are not given here and the reader is referred to the relevant web pages (below).

Tetraodon. This sequencing project was started at Genoscope in 1997 and they were joined by the Whitehead Institute for Genomic Research (WIGR) in June 2001. The approach taken was to end sequence a number of libraries containing different insert sizes: BAC (120–160 kb), cosmid (40 kb), and plasmid (4, 2.5, and 2 kb) libraries. The *Tetraodon* draft-sequence data is available on two sites, with an option on the French language version at Genoscope.

Genoscope: www.genoscope.cns.fr/externe/English/Projets/Projet_C/C.html

WIGR: www-genome.wi.mit.edu/annotation/Tetraodon

Takifugu. October 2000 saw the announcement by the US department of Energy that a consortium led by theJoint Genome Institute (JGI) was to completely sequence *Takifugu*. The consortium comprised groups from within the JGI, Molecular Sciences Institute, and Institute for Systems Biology in the US, along with MRC HGMP Resource Centre in the UK and the Institute of Molecular and Cell Biology in Singapore. This project mainly used end sequencing from a 2-kb plasmid library, but with additional sequence from a 5.5-kb plasmid library and BACs and cosmids. The *Takifugu* sequence information is available on four sites at the moment, all with different sequence viewers, although

the final official site is expected to be Ensembl.

4.2 Physical maps

The requirement for physical mapping has, to a large extent, been superseded by the genome information in which large areas of the genome are represented by sequence contigs. These contigs are available in several databases (detailed in Sect. 4.1) and are generally well annotated with gene homology information. Genome maps are however useful for confirming the integrity of whole-genome sequence assemblies and providing sequencing material in regions where there are gaps. Because pufferfish cannot be bred to produce genetic linkage maps, the only map prior to the sequence data was generated by physically linking genomic clones across chromosomes. In *Tetraodon*, this was performed in several complementary ways. Firstly, single copy probes derived from the ends of BAC clones were hybridized onto high-density colony membranes carrying 10-fold redundant coverage of the genome in BAC clones. This generated nearly 3000 clone contigs spanning about 60% of the *Tetraodon* genome. Then, the same BAC clones were digested with restriction enzymes and their electrophoretic profile compared (the ''fingerprinting'' technique) to examine the extent of their overlap. This approach produced approximately 2000 contigs independently from the hybridization method, and both sets were then merged to provide a structure onto which the assembled genome sequence could be layered and confirmed. This mapping information, together with added paired clone end sequences, was used to generate ''ultracontigs'' by linking together sequence scaffolds. Several hundred double-color *in situ* hybridizations on metaphase chromosomes were finally necessary to anchor these ultracontigs (generally 1 to 10 megabases in size) to the *Tetraodon* genome. A similar mapping program is currently ongoing for the *Takifugu* genome, using the clone fingerprinting technique.

4.3 Resources

There are quite a few genomic resources available for both pufferfish species, with additional cDNA libraries available for both *Takifugu* and *Tetraodon*. There is also a P1 artificial chromosome library available for a related pufferfish species, *Sphoeroides nephelus* (the Southern pufferfish). This comprises 30 000 clones, which is equivalent to 7 to 8 genome equivalents. These are all detailed below in Table 2.

5 Pufferfish as a Genome Tool

5.1 Comparative Genome Analysis in Vertebrates

With the current abundance of whole-genome sequence in both the prokaryote and eukaryote kingdoms, ''comparative genomics'' is a term increasingly used to

describe any approach where the sequence of two genomes (whole or partial) are compared to extract some knowledge about functional elements and the evolutionary processes that shape their sequences. Such studies were slow to take off in vertebrates because of the large genome size of the few species that were used as models or that were of interest to genome biologists (human, mouse, frog, zebrafish, chicken, etc.). The advent of sequencing projects in pufferfish changed this situation by providing a relatively economical and fast access to large regions of vertebrate genomes to be used in such comparative analyses.

The position of *Takifugu* and *Tetraodon* relative to mammals in the evolutionary tree is crucial to their importance as genome tools. The long divergence time since the split with tetrapods (approximately 400 million years) implies that functionally inert sequences that are submitted to a neutral rate of mutation have had time to diverge sufficiently to provide a good contrast with those that are functionally important and are thus submitted to purifying selection. This was empirically evidenced by the many small-scale analyses of regions sampled from the *Takifugu* genome and compared to their orthologous regions in human and sometimes mouse.

Initially, one of the reasons behind proposing the pufferfish as a model was the hypothesis that gene finding in human would be facilitated by a comparative positional cloning approach in a compact genome. For example, if the candidate disease region was 4 Mb in human, then by taking flanking markers to this region and mapping them to the pufferfish, this would equate to only 500 kb in the pufferfish. This left a much smaller region of DNA, in which to search, identify, and sequence the putative candidate disease gene. This relied on there being large-scale conservation of synteny between the pufferfish and human (the main reference organism). At the beginning of the 1980s, very little was known about gene-order conservation between vertebrates, so early pufferfish studies concentrated on these small-scale mapping studies. In retrospect, not surprisingly, there were many examples of conservation of synteny

between the pufferfish and human; however, many of these studies only encompassed two or three genes and often did not consider conservation of gene order. As larger data sets became available, it was clear that conservation of gene order over larger regions was rare (Fig. 4). Analysis of the *Takifugu* genome data showed that only 3.8% of the genome is in segments with no intervening sequences (perfect conservation of gene order between the pufferfish and human), while 5% is in segments with 1 intervening gene (mapping from a completely different human chromosome), 7% has up to 5 intervening genes, and 9.3% is in segments with up to 15 intervening genes. This is substantiated by mapping data in the zebrafish, which demonstrates large-scale conservation of synteny between zebrafish and human, at the whole chromosome level, but massive rearrangement of gene order between the two species. So the chance of finding a human candidate disease gene in the pufferfish by positional cloning is rare.

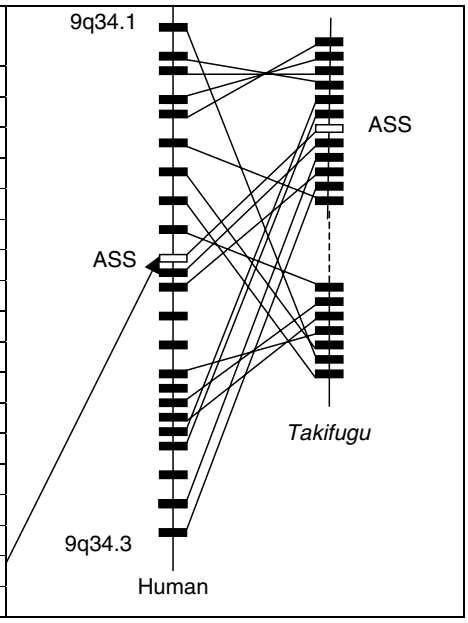

Fig. 4 Comparative mapping data from human chromosome 9, compared with *in situ* hybridization mapping data onto *Tetraodon* chromosomes (data taken from Gruetzner, F., Roest Crollius, H., Lutjens, G., Jaillon, O., Weissenbach, J., Ropers, H.H., Haaf, T. (2002) Four-hundred million years of conserved synteny of human Xp and Xq genes on three *Tetraodon* chromosomes, *Genome Res.* **12**, 1316–1322, with human map positions updated with Ensembl v.16.33.1) and also *Takifugu* BAC mapping data taken from Bouchireb, N., Gruetzner, F., Haaf, T., Stephens, R.J., Elgar, G., Green, A.J., Clark, M.S. (2001) Comparative mapping of the human 9q34 region in *Fugu rubripes, Cytogenet. Cell Genet.* **94**, 173–179. The data clearly shows that genes from human chromosome 9 are scattered across 12 different *Tetraodon* chromosomes. ASS, which maps to human 9q34.11, was mapped to a single *Takifugu* chromosome along with 2 BAC contigs containing 19 other human 9q34 genes. The diagram shows the rearrangements in gene order between the two species, which, in human, covers a region of 10 Mb.

There are exceptions to this general rule. At the gene level, there are the Hox complexes, and this is probably because of their coordinated expression in development processes. At the chromosomal level, there is some conservation of synteny of genes found on the human X. However, the X was almost certainly subjected to a special selection process during vertebrate development when compared with the rest of the chromosome complement. So, although one of the original reasons for studying the pufferfish is no longer robust, the pufferfish genomes have contributed significantly to our understanding of gene and chromosome evolution. Comparative analyses of human and pufferfish are still very useful for gene finding and also for promoter identification, as will be described in the following sections. As regards conservation of gene order between the two pufferfish, preliminary data indicates that they are nearly identical, which is not surprising when considering their close evolutionary relatedness.

Another way to exploit pufferfish genome sequence is to identify genes in other species. This became possible on a genome scale when the first samples of the *Tetraodon* WGS sequence became available. First, it was necessary to optimize sequence comparison algorithms so that the computing time required to compare a large fraction of vertebrate genome could be counted in days rather than months or years. Such parameters were thus adjusted using the BLAST sequence comparison algorithm so that about 40% of the human genome and 30% of the *Tetraodon* genome (the respective fraction of the two genomes available at the time) could be compared in about 5 days on a 100 CPU Unix cluster. The alignments produced were then filtered, on the basis of their length and their percent identity, so that only those that were thought to align over protein coding regions were retained. The criteria used in this selection were calibrated on known pufferfish and human genes. When several regions or sequence reads from *Tetraodon* overlapped on a given human region, this stretch of human DNA was dubbed an evolutionary conserved region (ecore). This first large-scale comparison between significant fractions of two vertebrate genomes produced a surprising result: the number of ecores estimated in the entire genome (once extrapolated from the 40% used in the comparison) was much lower than what would be expected if humans were to have the 80 000 to 100 000 genes given by previous estimates. Results from Exofish, the tool developed around the Human–*Tetraodon* comparison, suggested that the human genome contained between 28 000 and 34 000 genes, which is similar to the plant *Arabidopsis thaliana* and only five times more than the unicellular yeast. At the same time, this number was supported by a careful reanalysis of human EST sequence clusters, which suggested that the human genome contained no more than 35 000 genes. Today, with a finished sequence at hand, automatic annotation programs such as the Ensembl project have identified approximately 24 000 human genes and it is thought that few genes remain to be discovered. In fact, a comparison between the *Takifugu* draft genome sequence and an earlier version of the human genome suggested that less than 1000 human genes conserved between fish and mammals remained to be annotated.

Pufferfish genomes still have much to contribute to genome research. For instance, the human and mouse genomes are notorious for their abundance of transposable elements (approximately 45% of the genome). Conversely, probably the

main reason for the small pufferfish genome size is their paucity in repeats. This difference could be exploited to address a key question: how much DNA is under evolutionary selection in a vertebrate genome? Because this fraction is likely to be small, it cannot be easily measured against the background of neutrally evolving DNA represented by the repeats. In fact, a rough estimate indicated that approximately 5% of the mammalian genome could be under selection, when comparing the mouse draft sequence to the human. But aligning the two pufferfish genomes together may provide a much better answer, and, moreover, may indicate where these regions could be.

5.2 Functional Analyses Including Detection of Regulatory Elements

The ''classic'' gene functional analysis tools of transgenics, knock-ins, and knockouts are not possible in the pufferfish because of problems with breeding and size (in the case of *Takifugu*). Additionally, there has been only one pufferfish cell line made and so cell culture expression studies in ''same species'' is also not generally available. However, this will not hinder the exploitation of the pufferfish genomes. While characterization of pufferfish gene structure is valuable for gene identification (see Sect. 5.1), identifying conserved functional domains, understanding gene evolution processes, and to fish biologists working on other species, the main exploitation will be for the identification and characterization of conserved noncoding regulatory elements. Understanding gene function is the next stage for all genome projects and activity is obviously particularly strong in the mammalian field. Comparative analyses of mammalian genomes with those of the pufferfish can greatly advance this area of research.

The true extent of a gene, or rather functional unit, comprising coding regions, 5 and 3′ UTRs (untranslated regions), and regulatory elements can span many 100 kb in mammals. An example of this is the human *Sox9* gene, which is surrounded by 2 Mb 5′ and 500 kb 3′ of noncoding DNA. In *Takifugu*, these regions are reduced to 68 kb and 97 kb respectively, representing a considerable compaction of sequence. What exists in these noncoding regions between genes is only just being investigated; although, homology between species is generally very low when considering UTRs and these can be determined relatively easily by sequencing of full-length cDNAs or by RACE experiments. Regulatory regions are much more difficult to define, they are very small, often less than 10 bp in length, and may be at a considerable distance from the coding region of the gene they control. This is the real use of the pufferfish; because of their small genome size, the essential regulatory elements may also be squeezed much closer to the genes they regulate. Despite the evolutionary distance between the pufferfish and mammals, some of the regulatory sequences remain similar enough to those of mammals to be recognized by sequence comparisons and also to be functional in transgenic organisms. To identify and characterize a regulatory element, there are two requirements: that the regulatory elements are present in the DNA and that there is an assay system.

Recognition of regulatory regions can be determined using a variety of methods, such as BLAST sequence similarity searching, Clustal multiple sequence alignments, or purpose-built programs: Pipmaker (http://bio.cse.psu.edu/pipmaker), Vista (http://www-gsd.lbl.gov/vista), or

Dotter. Having determined that there are conserved regions between the pufferfish and mammals in a gene of interest, these then require experimental testing.

So far, use of pufferfish DNA in transgenics has had a mixed history, particularly with regard to the use of whole pufferfish genes. Success was achieved in rat for the *Takifugu* isotocin and oxytocin genes, but other examples, such as the HD and Wt1 genes, have resulted in aberrant splicing and nonfunctional products. The sequencing of the zebrafish genome and the increasing number of zebrafish facilities has opened up a new and potentially very powerful avenue for pufferfish research. While pufferfish genes may not generally splice correctly in mammals or mammalian cell lines, there appear to be no such problems in zebrafish, indicating that the aberrant splicing of pufferfish genes that occurs in mammals is related to evolutionary differences in splicing efficiency between fish and mammals. Having said that, it is the regulatory regions that are the real source of exploitation, rather than the actual genes themselves.

Pufferfish promoter regions have been inserted upstream of reporter constructs and expressed in a range of cell lines (mammalian and piscine). They have enabled the narrowing of regions responsible for the control of gene expression in genes as varied as the *Mx* protein (involved in the innate immune system), *Ick* (a lymphocyte-specific protein tyrosine kinase), *Pax 6* (involved in eye development), *tyrosinase* (pigmentation gene), and *SCL* (stem cell leukemia gene involved in hemopoiesis and vasculogenesis). This number of examples, currently rather limited, will dramatically increase over the next few years, as more groups access and mine the pufferfish data.

Pufferfish promoters have also been assayed, to a lesser extent, in transgenic animals. The *Takifugu* SCL locus directed appropriate expression to hemopoietic and neural tissue in transgenic zebrafish embryos and the Wt1 gene from the same species was faithfully expressed in the developing zebrafish kidney. Ick and Pax 6 *Takifugu* noncoding regions were successfully tested in transgenic mice. In the human *Pax 6* gene, there is a 3′ cis-acting regulatory element termed C1170Box123. This contains three modules in human and mouse, but only one in *Takifugu*. However, this one conserved module was assayed in mice, using both *Takifugu* and human 3′ constructs and both produced similar reporter gene-expression patterns. This latter example clearly demonstrates the point that not all regulatory regions will be conserved between fish and mammals. Indeed, this cannot be expected as there are considerable differences in morphology, physiology, and biochemistry between the two sets of species. Also, just because no homology is detected between mammalian and pufferfish promoter sequences, this does not mean that pufferfish 5′ regions cannot direct expression of mammalian genes. Although the *Takifugu* CRABP-1 promoter showed no homology to that of mouse, expression of the mouse gene was still obtained, but in a much more tissue-restricted manner.

Analysis of promoter elements using comparisons between species does rely on similarity of expression of the gene under study. Clearly there will be many examples between mammals and fish where this is not so, but fish also have an additional use, as regards dissection of promoter elements. It is well documented that fish have extra genes. It is thought that these duplicate pairs survive via the processes

of nonfunctionalization, neofunctionalization, and subfunctionalization. This duplication, which in many quarters is seen as a drawback of fish models, is actually very much an advantage. Comparison of duplicated genes between fish species and also with other vertebrates allows subfunction partitioning between the two genes, a situation that is not possible in mammalian models. Analysis of promoters between duplicated genes in fish can assign tissue- or developmental-specific functions to either or both of the pair of genes and can break up pleiotropic gene function and regulation. Few examples are available so far, but analysis of zebrafish, the two pufferfish, and *Xiphophorus*-duplicated *mitf* genes demonstrated subfunctionalization as a result of degeneration of alternative exons. This again is an area of investigation set to expand, particularly with regard to genes, which present in single copies in mammals are lethal when mutated. Mutations of such genes in fish are often still viable (as there are two copies) if only one of each duplicated pair is treated at any one time.

6 Prospects

The completion of the *Takifugu* and *Tetraodon* draft genome sequences mark a new step in the field of whole-genome sequencing in eukaryotes. Indeed, the first eukaryotes to be sequenced other than human (yeast, worm, fly, mustard weed, and mouse) were natural first choices: decades of laboratory experiments had accumulated a wealth of genetic and functional information, and their genome sequence was thought of as a conceptual framework in which to unify this diverse and heterogeneous data. In contrast, very little was known on the biology and life cycle of the two pufferfish described in this article. The reason for sequencing them lay exclusively in their position in the phylogenetic tree with respect to human and in their unusually small genome size. Their genome sequence has been a platform for gene discovery and genome comparisons.

But the *Takifugu* and *Tetraodon* genomes have not said their last word. Today, with the upcoming availability of the zebrafish genome sequence, it is expected that much will be gained by adequately combining functional tools developed in this species and comparative genomics tools represented by the pufferfish genomes.

Keywords

Algorithm
A defined rule for calculating output numbers from input numbers, usually carried out by a computer.

Gaussian (or Normal) Distribution
A distribution of values with the probability of the distribution being proportional to the distance squared from the mean.

Global Fitting
Fitting experimental data from various data sets to a single model function.

Least-squares Fit
Method of fitting experimental data to a function by minimization of the squared deviations of the experimental and theoretical points.

Model
An abstraction (usually a simplification) of the processes that are happening in a real system that allows the processes to be described in mathematical language.

Numerical Integration
Obtaining the value of an integral or the solution of a differential equation in a stepwise procedure using only numerical values.

Occam's Razor
Also known as the principle of parsimony, this means that other things being equal, the model or hypothesis with the smaller number of assumptions or parameters is to be preferred.

Parameters
Constant elements of a function.

Biochemistry is an experimental science characterized by an analytical and quantitative approach. Methods for the analysis of quantitative data are essential tools for handling the results of many biochemical studies. Some approaches are relatively straightforward and familiar to the biochemical community; others are more specialized, and their use is consequently less common. This chapter provides an account of two principal approaches to quantitative data analysis: least-squares fitting and regularization methods. A short summary of the theoretical background of these two approaches is followed by extensive coverage of applications taken from diverse areas including: enzyme kinetics, ligand binding, analytical ultracentrifugation, circular dichroism (CD), and the pH dependence of biochemical reactions. The discussion covers the nature of mathematical modeling of systems, and emphasizes the importance of selection of an appropriate physical model to describe the data.

1 Quantitative Data

The outcome of some biochemical experiments can be expressed as simple descriptive statements, such as "the desired band or peak was observed." In others, such as studies of the rates of processes or the affinity of a ligand for its target, the results need to be given in quantitative form as numerical values of one or more parameters. Such quantitative results are derived by mathematical analysis of the raw experimental data. As an example, consider the time course of an enzymatic reaction. The raw data are the dependence of product concentration (the dependent variable, conventionally shown on the *y*-axis) on the time (the independent variable, conventionally on the *x*-axis). The mathematical methods used to handle these and similar quantitative data can be of greater or lesser complexity depending on the processes involved and on the detail or depth of analysis required.

2 Numeric Modeling of Experiments

2.1 Formal Definition of the Mathematical Problem

This paragraph gives a formal introduction to the mathematical approaches most relevant to quantitative biochemical data analysis. For details on practical application, please refer to Sects. 2.2 and 3. In quantitative biochemical experiments, the outcome R can be described by a set of values usually expressed as real numbers. The elements of this set usually have all the mathematical properties of a function f, assigning the observable quantities (concentrations, spectroscopic signals etc.) to the independent variables $(x_i^1 \cdots x_i^n)$

(place, time, concentration of reactants ...) and constant parameters ($p_1 \cdots p_m$) (temperature, pH, buffer composition ...):

$$R = \{f_1(x_1^1 \ldots x_1^n; p_1 \ldots p_m), f_2(x_2^1 \ldots x_2^n; p_1 \ldots p_m), \ldots, f_k(x_k^1 \ldots x_k^n; p_1 \ldots p_m)\} \quad (1)$$

This general treatment can be simplified if one considers only a single observable. Then the result can be represented as an n-dimensional surface in $(n+1)$-dimensional space, created by the n-dimensions of the independent variables and one additional dimension for the experimental result. For further simplification, if there is only a single independent variable, this hypersurface is reduced to a situation that is much more familiar to a biochemist, that is, a set of points in a two-dimensional plot. One should, however, keep in mind that simply connecting these points with a continuous line introduces an assumption about the order of the functions and implies that one expects ''in-between'' functions that have not been measured. This procedure is only valid if there are good reasons to support this assumption, but fortunately this is more often than not true.

To illustrate this general function further, let us consider an enzyme kinetic measurement where the concentration of the product formed is measured as a function of time, while the enzyme concentration, initial substrate concentration, and temperature, as well as buffer composition are kept constant. In formal mathematical language this is expressed as follows:

$$c_{\text{Product}}(t) = f(t; c_{\text{Enzyme}}, c_{\text{Substrate}}^{\text{initial}}, pH, T, c_{\text{Buffer}})$$

In the experiment that we have just envisaged, time is the only independent variable, but repeating the experiment for different enzyme concentrations or initial substrate concentrations may introduce additional independent variables such that the complete experiment R consists of a set of time series of product concentration at different enzyme and initial substrate concentrations. Depending on the scientific question that is being posed, one also might vary the pH, temperature, or buffer composition. While in most experiments it is assumed that the independent variables and the constant parameters are known *a priori*, the values of these functions, which are the experimental results, are of course subject to experimental uncertainties, in other words – they are noisy. In obtaining such an experimental value, one is effectively taking a sample from a potentially infinitely large set of possible readings whose distribution reflects the experimental uncertainty. It follows, therefore, that statistical factors must be taken into consideration in any quantitative interpretation of results, a statement that will be all too familiar to anyone who has actually been involved in carrying out experiments and analyzing data.

Evaluation of such quantitative data is thus concerned with finding a suitable algebraic description for the earlier-mentioned functions to interpret it properly. The algebraic description that was used historically was a linear function, because then the only way of carrying out a regression analysis of data was fitting to a straight line. Data that were not themselves linear were transformed in such a way that they satisfied a linear relationship. Well-known examples of such transformations are the Scatchard analysis of binding data or Lineweaver–Burk analysis of enzyme kinetics. Unfortunately, all such linearization procedures inevitably

distort the experimental data by nonlinear transformation of the noise, which is one of the major sources of error in data interpretation.

Since computing power is now not a limiting factor and linearization of data is no longer necessary, or indeed desirable, algorithms have been developed that allow the direct analysis of the raw experimental data without the necessity of transformation. Basically, an algebraic model is devised that can simulate the unknown function that is being measured experimentally. Such a model should be based on physical considerations about the experiment, but it may also be partly or completely empirical. In addition to the independent variables ($x_i^1 \cdots x_i^n$) and constant parameters ($c_1 \cdots c_m$) of the experiment, such a model will also include some model parameters ($p_1 \cdots p_o$). These model parameters include physical constants, like rate constants or equilibrium binding constants whose determination usually is the aim of the experiment. The result of such modeling then is a set R_{Model} of numerical functions, ideally similar to those functions measured experimentally:

$$R_{\text{Model}} = \{f_1^{\text{Model}}(x_1^1 \cdots x_1^n; c_1 \cdots c_m; p_1 \cdots p_o), \cdots, f_k^{\text{Model}}(x_k^1 \cdots x_k^n; c_1 \cdots c_m; p_1 \cdots p_o)\} \quad (2)$$

There are essentially two strategies that can be used to find an optimal description of an experimental result:

In *fitting algorithms*, R_{Model} is used to describe the measurement directly and optimization procedures are used to find the set of model parameters ($p_1 \cdots p_o$) that best describes the experiment. The methods to find this optimal set will be discussed in Sect. 2.2.

Regularization methods can be exploited in circumstances where the fitting procedure is used to generate a best-fit function rather than values of individual parameters. In general, the fitting is carried out to a so-called describing function, which is of the following form $\int a(r) \cdot R_{\text{Model}}(r)\mathrm{d}r$.

$R_{\text{Model}}(r)$ is a function that depends on the nature of the experiment being undertaken. For example, for kinetic data it may be appropriate to take an exponential function of the form $R = a \cdot \mathrm{e}^{-t/\tau}$ where a (the amplitude of the function) and τ (its characteristic time dependence) are parameters used in the fitting algorithm. For ultracentrifuge data, the $R_{\text{Model}}(r)$ function is generally based on Lamm's differential equation expressing the concentration c as a function of distance (x) and time (t), the independent variables, and s and D are the sedimentation and diffusion coefficients, which are time and position independent parameters.

The other element of the describing function $a(r)$ is an arbitrary function whose form is part of the fitting procedure. Different criteria can be used to decide on the most appropriate form of the function $a(r)$. One that is commonly used is the maximum entropy principle, which selects the solution with the highest informational entropy, or alternatively expresses, the minimal information expressed as $\int (a \ln a)\mathrm{d}r$. The rationale for this criterion is that, according to Occam's razor, the solution with the highest parsimony is to be preferred, a view that can be justified by Bayesian statistical arguments. In operational terms, it is important that the quality of the fit to the data should be balanced against any constraints such as maximum entropy or parsimony requirements.

As an example, one might envisage an exponential function $R = a \cdot \mathrm{e}^{-t/\tau}$. In this

function, both a and τ are the parameters that would be used in a fitting algorithm. However, a describes the height of the function (or its intensity) and τ describes the shape (or its steepness). The describing function is defined as $\int a(\tau) \cdot e^{-t/\tau} d\tau$. Since τ will now take all possible values (in practice the range will be limited) only $a(\tau)$ is left as an arbitrary function to be calculated to describe the experiment best. It is interesting to note that this procedure represents a projection of the experimental data onto $a(\tau)$. For example, a sum of three exponential functions $R = \sum_{i=1}^{3} a_i e^{-t/\tau_i}$ would result in an $a(\tau)$, which has the value of a_i at τ_i and zero everywhere else. Provencher in 1982 had given a full description of this method, and the same is also illustrated later in this chapter (Sect. 3.12) in an analysis of the sedimentation behavior of protein mixtures in the analytical ultracentrifuge that was first described by Schuck in 2000.

2.2 Fitting

Regardless of the strategy used, data evaluation by modeling involves searching for a numerical model that best describes the experimental data according to some suitable criterion. The questions that arise when data are being analyzed quantitatively are essentially the following:

- How well does the model under consideration, which is usually proposed on the basis of previous experience, perform in explaining the experimental data, bearing in mind the accuracy of that data? Is the model satisfactory, or is it necessary to consider alternatives?
- What values of the parameters characterizing the system (rate constants, equilibrium binding constants etc.) are most consistent with the experimental data?
- How accurate are these parameters, and what are the limits of error?

There are several important criteria that all procedures for data analysis should satisfy, chiefly that:

- the experimenter should be able to see the results of the analysis graphically to check whether they are reasonable, and get a feel for the accuracy;
- however the results are manipulated, the original raw data should not be lost;
- there should be no hidden error propagation in the operations, for example, by using transformations involving $1/x$, y^x and similar functions.

The most widely used criterion for judging the quality of description or fit of the data by a model is the least-squares criterion where the sum of squared deviations (SSD) or the root mean square deviation (RMSD) is a minimum for a given parameter set.

When having o parameters and k data points we obtain:

$$SSD(p_1 \cdots p_o) = \sum_{i=1}^{k} \left[f_i^{\text{Model}} - f_i^{\text{measured}} \right]^2$$

$$RMSD(p_1 \cdots p_o) = \sqrt{\frac{1}{k} \sum_{i=1}^{k} \left[f_i^{\text{Model}} - f_i^{\text{measured}} \right]^2} \qquad (3)$$

If the original experimental measurements are normally (Gaussian) distributed around the ''true'' value, then such a minimization will lead to a parameter set of maximum likelihood. This set of parameters can be interpreted as the result of the experiment.

However, it should be borne in mind that the least-squares criterion is only one

possible criterion of fit, and other criteria exist, which can be expressed by using the following more general definition of model deviation D:

$$D(p_1 \ldots p_o) = \sum_{i=1}^{k} |(f_i^{\text{Model}} - f_i^{\text{measured}})|^n \tag{4}$$

where n can be any real number. In case of $n = 1$ the fitting procedure is called *robust fitting*. Robust fitting can be of advantage whenever the sampled measurements are not distributed in a Gaussian manner, but contain some ''outliers'' (Johnson, 2000).

The basic concepts underlying the methods of data analysis discussed here are illustrated in Fig. 1. The results of an experiment are data. A model is a description of the processes taking place in the experimental system being observed, which defines a mathematical relationship between the independent variables and the results. The model also defines physical parameters as variables to be fitted or used in regularization. With plausible initial values of the parameters, the mathematical relationships are used to obtain simulated data, which are compared with the experimental data. The values of the parameters are then varied until an optimal fit is obtained of the simulated and experimental results.

In the following sections, the basic concepts of quantitative data analysis are discussed, together with the terms used in Fig. 1.

2.3 Experimental Systems

The system is made up of various components and species. ''Components'' are molecules that differ in their covalent structures, for example, enzyme, substrate, and product; components can interact to form complexes, for example, an enzyme–substrate complex. ''Species'' are all the entities present in the solution that differ in either their covalent or

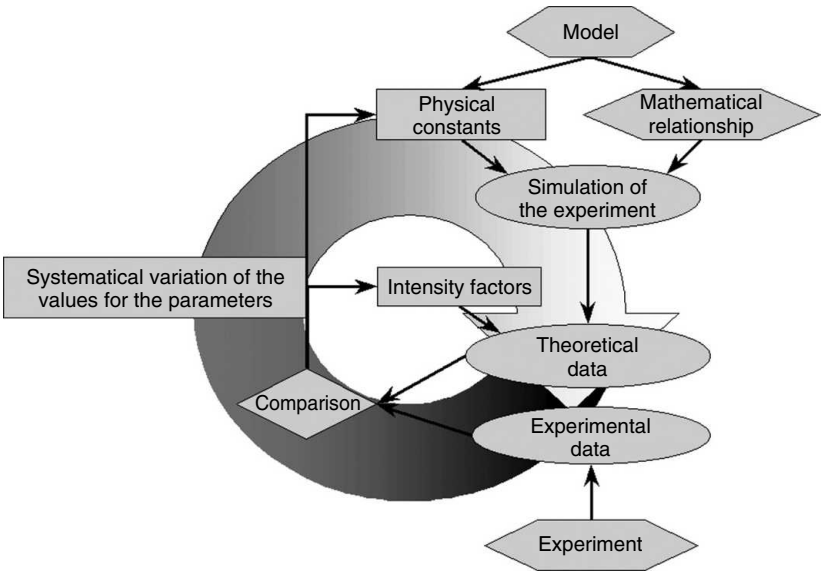

Fig. 1 Schematic illustration of fitting procedures used for quantitative data analysis.

noncovalent structures; this will include components, complexes, and where relevant, different conformations of these.

2.4 Measurement and Signals

In our analysis, we consider a general relationship between the measurement or "signal" and the composition of the solution; the signal is the experimental quantity being measured, which gives information about the processes taking place. It is assumed that the total measured signal is additive in terms of the contributions of all of the species (i) in the solution, and furthermore, that the signal from each species is proportional to its concentration (c_i). Different species contribute in differing extents to the total signal, and the proportionality constant (f_i) is termed *the intensity factor* of the species i. This intensity factor defines the relationship between the concentration of the species and the measured signal (e.g. CPM, absorbance, fluorescence intensity, etc.). It is usual to have to take account of a nonspecific but constant background signal, which we here define as the *baseline* (BL). Thus, the observed signal is given by:

$$S = BL + \sum_i f_i c_i \tag{5}$$

In many cases, this expression simplifies by using the mass conservation laws. So, for example, if we have the species A, B, that form AB in solution, then the signal is given by the expression

$$\begin{aligned} S &= BL + f_A c_A + f_B c_B + f_{AB} c_{AB} \\ &= BL + f_A c_A^0 + f_B c_B^0 + (f_{AB} - f_A - f_B) c_{AB} \\ &= C + f c_{AB} \end{aligned} \tag{6}$$

with only a single intensity factor and a constant term. To simplify the analysis, and to make the numerical analyses more stable, it is important that realistic assumptions are made about which species contribute to the signal, for example, in the case of radioactive detection, only those species that are labeled.

2.5 Models

As described in the mathematical definition section, a model represents an abstraction of the processes that are happening, or could be happening, during the experiment. From this model, we can derive a mathematical relationship between the experimental results and the independent variables. Consider the simple case of the two species A and B forming a complex AB in a time-dependent process:

$$c_{AB} = f(t, c_A, c_B)$$

The experimental results would be the concentrations c_{AB}, and the independent variables would be c_A, c_B, and the time t.

The model provides specific parameters for the fitting process, enabling theoretical data to be evaluated. These can be calculated either analytically or numerically. If the mathematical relationship between the signal (observation) and the parameters is sufficiently simple, it may be possible to obtain analytical solutions and calculate the theoretical signal directly, that is, in the present example to obtain values of c_{AB} knowing the initial concentrations of the concentrations c_A^0, and c_B^0, and the time t.

However, in many cases, the mathematical relationships are not that simple, and analytical solutions may either not be possible in principle, or be too difficult and cumbersome in practice. In such cases,

the theoretical data can be simulated by numerical methods.

A model is, of course, only a working hypothesis, whose validity is judged by its success in accounting for the data. If its performance is not satisfactory, then alternative models should be sought or devised. However, if a model is to be replaced by a more complicated one, then it is important to check that the data really warrant this. More complicated models generally have more parameters, and more parameters will always lead to better fitting of the data. One should be guided here by the Principle of Parsimony, that other things being equal, the preferred model is the simplest one with the fewest parameters.

2.6 Selection of Appropriate Models

The choice of the right model to be used to describe experimental results is one of the trickiest and most interesting tasks in scientific work, and this is a subject that can only be touched on here. As discussed earlier, we are guided by the Principle of Parsimony that in science one should seek the simplest explanation for phenomena. In the present context, it means that we should define models with as few parameters as possible, consistent with obtaining a satisfactory description of the data. This is a sensible approach, because if a simple model fits the data adequately, then so necessarily must more complicated versions of that model. It follows that experimental observations can only serve to rule out models often, but not always, because they are oversimplified; the data can never prove that a model is correct. The question naturally arises at this stage about how one can establish whether a model is successful in accounting for the data or not. There are several criteria for assessing the quality of a model.

- The absolute magnitude of the deviations between the theoretical and experimental data. Does the theoretical curve lie in the region of experimental uncertainty of the data points (taking particular care not to overestimate the accuracy of the data)?
- The direction of the deviations between the theoretical and experimental data. Are the deviations randomly distributed, sometimes above and sometimes below the curve, or are they clustered, above the curve in one region and below in another? If the deviations are not randomly distributed, this indicates that the theoretical curve is not a satisfactory fit to the experimental data. One reason for this is that the model is wrong and is not an adequate description of the situation; another is that systematic errors have been made in carrying out the experiment.
- Whether alternative models are available, which can account for the data more satisfactorily.

A good model should also have predictive power and suggest additional experiments that can be carried out to test the model further.

2.7 Parameters

Depending on the model under consideration, one obtains a set of parameters that establish the relationship between the experimental data and the assumptions underlying the model. It is important to distinguish two kinds of parameters: global and local. This distinction is important when several data sets are being

considered jointly in the analysis; the values of the global parameters must be the same in all cases, whereas, those of the local parameters may vary from one data set to another.

- Global parameters: the values of the global parameters are the same for all of the data sets that are being considered in the analysis. We are dealing here with physical quantities such as binding or rate constants whose values we wish to determine.
- Local parameters: the values of the intensity factors discussed earlier can differ from experiment to experiment. Examples of intensity factors are: radioactivity ($CPM = f_i \cdot c_i$), fluorescence intensity ($signal = f_i \cdot c_i$), absorbance spectroscopy ($OD = f_i \cdot c_i$, where f_i is the extinction coefficient of species i), ELISA ($signal = f_i \cdot c_i$), and so on. Although the precise values of these factors, which are local parameters, often are not particularly interesting in understanding the system, they are needed for the analysis.

2.8 Essential Steps in the Analysis

There are three basic steps in every data analysis (cf. Fig. 1):

- arbitrary initial values of the parameters are introduced into the model to calculate theoretical concentrations for all of the species of interest in the system.
- these theoretical concentrations are combined with initial values for the intensity factors to obtain theoretical values for the measurement or signal.
- the values of the parameters and intensity factors are varied to obtain the best fit of the theoretical values of the signal to the experimental values; the combination of parameters that best fits the data is the result of the analysis.

2.9 Fitting Data by the Method of Least Squares

The classical method for fitting data to theoretical curves is linear regression. This procedure allows the equation of the best straight line fitting a set of experimental data to be calculated directly:

$$y = a + bx$$

$$\text{slope } b = \frac{n\sum xy - \left(\sum x\right)\left(\sum y\right)}{n\sum x^2 - \left(\sum x\right)^2} \quad (7)$$

$$y \text{ intercept } a = \frac{\left(\sum x^2\right)\left(\sum y\right) - \left(\sum x\right)\left(\sum xy\right)}{n\sum x^2 - \left(\sum x\right)^2}$$

Until relatively recently, this was the only method that could be used conveniently to fit data by regression. This is the reason why so many classical approaches for evaluating biochemical data depended on linearizing data, sometimes by quite complex transformations. The best-known examples are the use of the Lineweaver–Burk transformation of the Michaelis–Menten model to derive enzyme kinetic data, and of the Scatchard plot to analyze ligand binding equilibria. These linearization procedures are generally no longer recommended, or necessary.

In contrast to the explicit analytical solution of "least-squares fit" used in linear regression, our present treatment of data analysis relies on an iterative optimization, which is a completely different approach: as a result of the operations discussed in the previous section theoretical data are calculated, dependent on the model and

choice of parameters, which can be compared with the experimental results. The deviation between theoretical and experimental data is often expressed as the sum of the errors squared for all the data points, alternatively called the *sum of squared deviations* (*SSD*):

$$SSD = \sum_i (S_{i,\text{exp}} - S_{i,\text{theo}})^2 \qquad (8)$$

This deviation is now minimized by variation of the parameters. The combination of parameter values that best fit the experimental data – using this deviation as the criterion of best fit is the desired solution of the analysis. This process of finding a solution is termed *iteration* because the solution is located by trying out many possible combinations of parameters; since the equations being fitted are in general nonlinear, the process is more specifically one of the iterative nonlinear least-squares fitting.

The process is essentially as follows. All possible combinations of the parameters (physical constants and intensity factors), of number N, define an $(N+1)$-dimensional error space. Every point in that space has a characteristic value of the sum of the squared deviations or SSD, which thus generates an error surface in $(N+1)$-dimensional space. If, for simplicity, we consider a model with only two parameters, these can be represented on the x- and y-axes, and the value of SSD on the z-axis. The error surface is now simply a surface in conventional three-dimensional space. An even simpler example with one parameter is illustrated in Fig. 2, where the parameter is shown on the x-axis and the SSD is on the y-axis. The task in the fitting procedure is to locate the minimum value in the SSD curve (region A in Fig. 2). It is impracticable to try out all possible values of the combined set of parameters, particularly when there are many of them. The procedure adopted in most computer programs is, starting from initial values of the parameters (provided by the user) calculations are made of the slope (or derivative) of the error surface in $(N+1)$-dimensional space. This is done by making a small variation in each of the parameters in turn, and calculating the SSD. The program then locates the region where the slope is steepest (downwards) and it alters the parameters by a small step in that direction to generate a new set of parameters, which fit the data better. From this new set of parameters, the program repeats the operation in a second iterative cycle to locate the direction of steepest descent, and hence a new set of parameters.

This procedure depends on certain features that merit comment.

- The step length in the iteration is critical: if it is too short, then the process of

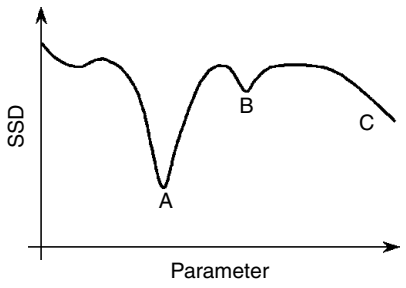

Fig. 2 Two-dimensional representation of an error surface. Region A is the location of the global minimum, region B is a local minimum, and region C represents an area where the model is no longer valid and the slope of the error surface is directed away from the minimum.

locating the minimum takes too long, whereas, if the step length is too long the algorithm used in the program can miss the target area, and thus never locate the minimum. The SOLVER algorithm used in Excel selects the step length automatically depending on the slope of the error surface and the result of the previous round of iteration.

- The ''result'' located by the program can be a local minimum (e.g. region B in Fig. 2). Locating the global minimum is often not straightforward, particularly when the error surface is complex, and the program can find itself trapped in a local minimum. The best means of avoiding this, or at least detecting when it is happening, is to begin the iteration process from different initial parameter estimates, and check whether the same solution is found in every case. If this does not happen, the solution with the lowest SSD corresponds to the best solution, although it should be noted that in some cases alternative solutions might be equally good in terms of their *SSD* values, bearing in mind the accuracy of the experimental data.
- To avoid local minima, most algorithms also test randomly selected points in the error surface. The extent to which a program carries out these tests determines the speed of locating the minimum and the tendency of the algorithm to become trapped in local minima.

All models have limits to their region of validity; for example, negative values of rate or binding constants do not correspond to physically meaningful situations. In such regions, mathematical errors will arise, such as attempting to find the square root of a negative number, even though all of the equations have been correctly programmed.

The slope of the error surface can lead the iterations into regions that are remote from the minimum. This situation can readily lead to failure to locate the minimum when the initial parameter estimates are not very good. To remedy this, a fresh set of initial estimates should be selected, which fit the data better. In Fig. 2, for example, it would be difficult to locate the minimum if the program started in region C since the slope in the error surface is pointing in the wrong direction.

The usual criterion of ''best fit'' is the sum of errors squared (the *SSD* discussed earlier) rather than the absolute magnitude of the errors. This procedure is mathematically justified when the errors in the data follow the Gaussian (or normal) distribution. Under these conditions, the error distribution function is given by the following equation in which x is the measurement, μ the mean, and σ the standard deviation:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \qquad (9)$$

When the data are distributed according to this function, the frequency of occurrence of data falls according to the square of the deviation. In practice, the sum of error square (*SSD*) criterion is also used in cases where it has not been explicitly established that the errors are normally distributed, and it appears to function quite well.

2.10 Global Fitting of Multiple Data Sets

If different sets of experiments have been carried out under circumstances in which the observations depend on a common set of parameters, then it is sensible to attempt a global fitting of the data sets to

obtain best estimates of the parameters. It is important here to distinguish clearly between the global and local parameters discussed earlier (Sect. 2.7). The global parameters are valid for all of the data sets and are fitted to all of the data, whereas the local parameters may assume different values for the various data sets. For example, if one were investigating a thermodynamic equilibrium, and monitoring the process using radioactive detection, the value of the equilibrium constant must be the same under the same conditions, whereas the specific activities of the reaction participants could well be different. In global data fitting, it is particularly important to keep the number of parameters as small as possible. There are two reasons for this. First, the general consideration that following the Principle of Parsimony one should seek to account for experimental data using the smallest number of variables. Second, that iterative fitting of the data becomes much more difficult (in fact, exponentially so) as the number of variables increases; the process becomes much slower, and there is an increasing risk that local minima will interfere with the fitting. To keep the number of parameters as small as possible, it is important to check, in particular, whether all of the local parameters are needed. For example, in the general case, it is assumed that all of the reaction participants contribute to the experimental signal or measurement, but if this is not in fact true, then it is better to set the intensity factors of as many species as possible to 0, and only allow the minimum necessary number of species to contribute to the signal. For example, in studies based on fluorescence detection, only species containing a fluorophore need to be assigned intensity factors.

One difficulty that can arise in global data analysis is that the signal intensities of different data sets can be very different. If the data are treated equally, this can lead to the situation that data sets or curves with high intensities completely dominate those with lower intensities, simply because their error squared parameters (SSD) are so much larger. The most effective way of dealing with this situation is to weight the SSDs of the different data sets or curves by a suitable factor, for example, by the mean value of the data set, or by the relevant intensity factor. It should be emphasized that weighting factors must never be treated as variables in the fitting process.

2.11 Introduction to Error Estimation

One of the most difficult tasks in day-to-day scientific activity is making reliable estimates of the errors and uncertainties in the data. How reliable are my data? How accurate are the parameters calculated from them? Can I, or should I, exclude particular models for explaining my data? These are examples of the sort of questions that need to be asked. We have already discussed the question of judging how well models perform in accounting for data; we now turn to the question of assessing accuracy, on the basis that the model used is an appropriate one. It should be noted that we are dealing here with statistical errors and the treatment of outliers; systematic errors cannot be detected by these approaches.

Statistical analysis of repeated measurements. If a very large number of data are available, then it is sensible to consider carrying out a rigorous statistical analysis. The simplest procedure is to do many replicates

of the same experiment (or series of experiments, if more than one data set is needed for the analysis) and then analyze them independently. This is a very good way of assessing the error range (determined as standard deviations, maximal range etc.) of the individual parameters; the problem is the amount of work involved.

The accuracy of individual measurements. We are concerned here with the problem of assessing accuracy when the number of available data is limited. One means of gauging error is to remove individual data points from the fitting process to get a feel for the "robustness" of the data. In effect, what this process does is to analyze the data on the assumption that the single experiment removed had not been carried out. It is possible in this way to assess how reliable the data are, and specifically to determine whether the outcome was highly dependent on the single result, implying that one would need to be very sure about it. This form of analysis is straightforward and revealing, and it ought to be a part of every data evaluation.

Analysis of error surfaces. To conclude this section, we consider a more quantitative approach to error estimation. The first step is to estimate the accuracy of the individual data points; this can either be done by analysis of the variability of replicate measurements, or from the variation of the fitted result. From that, one can assess the shape of the error surface in the region of the minimum. The procedure is straightforward: the square root of the error, defined as the *SSD*, is taken as a measure of the quality of the fit. A maximum allowed error is defined, which depends on the reliability of the individual points, for example, 30% more than with the best fit, if the points are scattered by about 30%. Then each variable (not the *SSD* as before) is minimized and also maximized. A further condition is imposed so that the sum of errors squared (*SSD*) should not increase by more than the fraction defined earlier. This method allows good estimates to be made of the different accuracy of the component variables, and also enables accuracy to be estimated reliably even in complex analyses. Finally, it reveals whether parameters are correlated. This is an important matter since it happens often, and in some extreme cases where parameters are tightly correlated, it leads to situations where individual constants are effectively not defined at all, merely their products or quotients. Correlations can also occur between global and local parameters. This issue is illustrated in Fig. 3, where a set of initial slopes of an enzyme reaction are analyzed using the Michaelis–Menten model (see Sect. 3.2, Eq. 12). Since K_m is defined using v_{max}, depending on the shape of the curve any change of v_{max} will cause a certain change of K_m as well.

2.12 Introduction to Numerical Integration

Kinetic processes can be described by differential equations; for example,

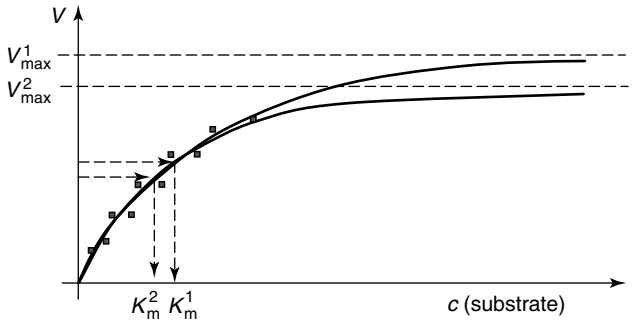

Fig. 3 Illustration of the origin of correlation of parameters with the example of a Michaelis–Menten analysis of steady state kinetics data. In this example, there is a strong correlation of k_{cat} and K_m.

for a reversible bimolecular association reaction:

$$A + B \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} AB$$

is described by

$$\frac{\partial c_{AB}}{\partial t} = k_1 c_A c_B - k_{-1} c_{AB} \qquad (10)$$

This equation defines directly the change in concentration of the species AB with given concentrations of the reactants A and B, and the product AB. This is a differential equation whose solution is an expression of the form $c_{AB} = f(t, c^0_A, c^0_B)$. The solution involves a process of integration, which is often difficult, and sometimes impossible, at least analytically. In such cases, numerical integration can be used to simulate the time-dependent variation of c_{AB} in an experiment, enabling theoretical data to be obtained even for complex systems.

The procedure for numerical integration is as follows. Initial conditions are first selected: c^0_A, c^0_B, c^0_{AB} and from this initial state the concentrations of the three component species are altered stepwise using "fluxes" defined from the differential equation given earlier, with a finite time increment Δt.

Two different fluxes exist:

F_1:"association," A + B

$\longrightarrow$ AB for which $F_1 = k_1 c_A c_B \Delta t$

F_{-1}:"dissociation," AB

$\longrightarrow$ A+B for which $F_{-1} = k_{-1} c_{AB} \Delta t$ (11)

The concentration changes are defined in terms of these fluxes as follows:

$$\Delta c_A = -F_1 + F_{-1}$$

$$\Delta c_B = -F_1 + F_{-1}$$

$$\Delta c_{AB} = -F_{-1} + F_1$$

from which new concentrations are obtained using the following general expression, where $c_{i,old}$ is the "old" concentration of the species (i) before the incremental change Δc_i:

$$c_i = c_{i,old} + \Delta c_i$$

The formulae given in Eq. (11) are prototypes for bimolecular (F_1) and monomolecular (F_{-1}) elementary reactions respectively. By combining these

prototype equations, kinetic schemes of any desired complexity can be described and analyzed. The time interval is a critical parameter in the integration process, if it is chosen too short, the process takes too long, if it is too long, the process is inaccurate.

3 Applications

3.1 Linear Regression

Situations arise very often where data need to be fitted to linear equations. Linear regression is one of the classical procedures in general regression analysis, and before the advent of accessible nonlinear fitting methods it was the only one that could be readily used. For n data pairs in the form (x, y) where y is a function of x, the linear equation of the form $y = a + bx$ that minimizes the sum of errors squared (SSD) is given by Eq. (7).

3.2 Michaelis–Menten Kinetics

The Michaelis–Menten model shown below is the simplest mechanism for describing the kinetics of enzyme catalyzed reactions:

$$S + E \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \longrightarrow E + P$$

According to this mechanism, the rate constant for the reaction k (dimension: time^{-1}) depends on two parameters: K_m and k_{cat}. In the simple mechanism shown earlier and with the assumption that ES is in a steady state, $K_m = (k_2 + k_{-1})/k_1$ and $k_{cat} = k_2$. The dimensions of K_m and k_{cat} are concentration and (time)$^{-1}$ respectively. The rate of the reaction v (dimension: concentration/time) is given by the expression $v = kc_{E,total}$, and v_{max} is equal to $k_{cat}c_{E,total}$. The dependence of the reaction rate constant (k) on substrate concentration is given by Eq. (12), from which it can be seen that the K_m value is the concentration of substrate that gives half of the maximum rate k_{cat}.

$$k(c_S) = k_{cat}\frac{c_S}{c_S + K_m} \qquad (12)$$

To evaluate K_m and k_{cat}, the rate of reaction is measured as a function of substrate concentration and the two kinetic parameters are determined using Eq. (12). The classical method of doing this is by fitting the data to a linearized form of Eq. (12) such as the Lineweaver–Burk plot shown in Eq. (13):

$$\frac{1}{k(c_s)} = \frac{1}{k_{cat}} + \frac{K_m}{k_{cat}}\frac{1}{c_s} \qquad (13)$$

From this it follows that a plot of $1/k$ against $1/c_S$ should give a straight line with an x-intercept of $-1/K_m$ and a y-intercept of $1/k_{cat}$. The Lineweaver–Burk analysis illustrates very clearly the sort of problem that can arise when dealing with linearized data. An assumption that underlies simple linear regression following the procedure discussed in the previous section is that all of the data points have the same error, or specifically, standard deviation. This assumption is no longer valid when the data are transformed as is shown in the following diagrams.

Figure 4(a) illustrates a series of measurements where all the data have the same error; in Fig. 4(b), the same data are shown after transformation for Lineweaver–Burk analysis. It can be seen that the data points at low concentration (i.e. at high values of $1/k$ and $1/c_s$) have a much higher error than the other points, and the situation

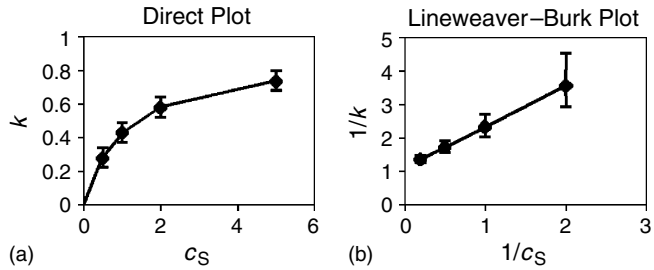

Fig. 4 Error propagation in the direct analysis and Lineweaver–Burk analysis of Michaelis–Menten kinetics.

is made worse because these inaccurate points are also the ones that exert the most leverage on the linear regression, and hence on the derived kinetic parameters. A very comprehensive analysis of the kinetics of enzyme catalyzed reactions has been presented by Bisswanger in 2000.

3.3 Analysis of Circular Dichroism Experiments to Determine the Secondary Structure Composition of Proteins

Circular dichroism (CD) is the spectroscopic method of choice to investigate the secondary structure of proteins. The CD spectrum of a protein is given by the sum of the contributions of its α-helical, β-sheet, β-turn, and disordered ("random") structural elements. The results of CD experiments can be analyzed very simply to provide information about the fraction of α-helical, β-sheet, β-turn, and random regions in a protein. The analysis depends on comparison of the CD spectrum with reference spectra for the respective secondary structure elements, which are derived from the CD spectra of a large set of proteins of known structure. Then, the CD signal is given by:

$$\theta(\lambda) = c_P(f_\alpha \varepsilon_\alpha^{ref} + f_\beta \varepsilon_\beta^{ref} + f_t \varepsilon_t^{ref} + f_r \varepsilon_r^{ref}) \quad (14)$$

where c_P is the concentration of the protein, f_α, f_β, f_t, and f_r denote the fractions of the protein in α-helical, β-sheet, turn and random conformation, and ε_i^{ref} is the extinction coefficients of the respective secondary structure element taken from the reference spectra. For analysis, $\theta(\lambda)^{theo}$ is fitted to $\theta(\lambda)^{exp}$ by variation of f_α, f_β, f_t, and f_r.

3.4 Dissociation Kinetics

Dissociation reactions of the general form $AB \rightarrow A + B$ are monomolecular processes, where the rate of decay of the complex is proportional to its concentration. The concentration dependence of c_{AB} is given by the following differential equation:

$$\frac{dc_{AB}}{dt} = k_{-1} c_{AB}$$

which on integration yields Eq. (15), where $c_{AB}(t)$ is the concentration of complex at any time t, and c_{AB}^0 is the initial concentration at time $t = 0$:

$$c_{AB}(t) = c_{AB}^0 e^{-k_{-1}t} \quad (15)$$

Analysis of dissociation processes yields values for the rate constant k_{-1}, whose dimensions are $(time)^{-1}$. This rate constant is related to the lifetime (τ) of the complex AB by the expression $\tau = (k_{-1})^{-1}$, and

to the half-life ($t_{1/2}$) by the expression $t_{1/2} = (\ln 2/k_{-1})$.

3.5 Binding Data

The equilibrium constant for a simple bimolecular association process

$$A + B \overset{K_{Ass}}{\rightleftharpoons} AB$$

is defined by the expression:

$$K_{Ass} = \frac{c_{AB}}{c_A c_B} \tag{16}$$

This equilibrium constant is expressed as the association constant, which has dimensions $(concentration)^{-1}$, in molar terms M^{-1}. The dissociation constant K_{Diss} is the reciprocal of K_{Ass} and has dimensions of concentration (M). The objective of the following derivation is to obtain an equation of the form $c_{AB} = f(c_{A,tot}, c_{B,tot}, K_{Ass})$, where $c_{i,tot}$ is the total or stoichiometric concentration of the component i (which is known), in contrast to the quantity c_i in Eq. (16), which is the free concentration of the species in solution, which is not known. An equation of this form will enable us to calculate the theoretical data.

Using the conservation conditions: $c_{A,tot} = c_A + c_{AB}$ and $c_{B,tot} = c_B + c_{AB}$ Eq. (16) can be written in the form:

$$K_{Ass} = \frac{c_{AB}}{[(c_{A,tot} - c_{AB})(c_{B,tot} - c_{AB})]} \tag{17}$$

The only unknown in this equation is the term c_{AB}. Expanding and rearranging Eq. (17) yields the following quadratic equation:

$$c_{AB}^2 - \left(c_{A,tot} + c_{B,tot} + \frac{1}{K_{Ass}}\right) c_{AB} + c_{A,tot} c_{B,tot} = 0$$

The solutions of a quadratic equation of the general form $x^2 + px + q = 0$ are given by the two roots x_1 and x_2:

$$x_{1,2} = -\frac{p}{2} \pm \sqrt{\left(\frac{p}{2}\right)^2 - q}$$

In the present case, only the negative square root term is physically meaningful, so the concentration of AB is given by the following equation:

$$c_{AB} = \frac{c_{A,tot} + c_{B,tot} + 1/K_{Ass}}{2} - \sqrt{\left(\frac{c_{A,tot}+c_{B,tot}+1/K_{Ass}}{2}\right)^2 - c_{A,tot} c_{B,tot}} \tag{18}$$

To determine values of K_{Ass} binding data are needed, where the total concentrations of either A or B are comparable in magnitude to $1/K_{Ass}$.

3.6 Independent Identical Binding Sites

The earlier-mentioned model and equations have to be modified if one of the species (say A) has several binding sites for the other species B. If the binding sites are independent and do not interact, then binding to each site on A can be described by Eq. (19). Taking all of the binding sites into account yields a hyperbolic binding curve whose binding equation only differs from Eq. (18), where for every molecule of A, n binding sites exit such that the total concentration of binding sites is $nc_{A,tot}$:

$$c_{B,bound} = \frac{nc_{A,tot} + c_{B,tot} + 1/K_{Ass}}{2} - \sqrt{\left(\frac{nc_{A,tot}+c_{B,tot}+1/K_{Ass}}{2}\right)^2 - nc_{A,tot} c_{B,tot}} \tag{19}$$

To obtain accurate estimates of the number of binding sites (n), binding experiments (usually titrations) need to be performed under conditions where the total concentration of A is relatively high, specifically that $c_{A,tot} \gg 1/K_{Ass}$; these conditions define a ''stoichiometric titration'' where, effectively all of the B added is bound until the sites on A are saturated (see Fig. 5). Titrations under these conditions are insensitive to the value of the association constant, so to obtain reliable estimates of K_{Ass}, data are needed from titrations at much lower concentrations, where $c_{A,tot} \leq 1/K_{Ass}$. It should be clear from this discussion that it is not easy to evaluate both n and K_{Ass} accurately, and it is usually necessary to do a global analysis of several data sets, obtained under different concentration conditions.

3.6.1 Analysis of Simple Binding Data

The equation for n identical, noninteracting binding sites (Eq. 19) is in principle soluble, although the solution is not straightforward. When binding is more complex and the sites are of different affinity and interacting, then analytical solutions cannot be obtained. However, analysis of the binding can be simplified by carrying out experiments under conditions where one of the interacting partners (say A) is present at a much lower concentration than the other. The concentration of the partner in excess (B) is varied, and the proportion of available binding sites on A, which are occupied ($c_{AB}/c_{A,tot}$) is measured. The simplification in the analysis arises because the free concentration of B can be taken to be the same as the total concentration (since $c_{AB} \ll c_B$). Equation (16) can be simplified considerably yielding, after inserting the conservation condition for A and rearrangement:

$$\frac{c_{AB}}{c_{A,tot}} = \frac{c_B K_{Ass}}{1 + c_B K_{Ass}} \qquad (20)$$

3.6.2 Independent Nonidentical Binding Sites

Consider a macromolecule A that can bind several molecules of B. In the simplest case, where A possesses two binding sites for B, there are four possible species, A, AB, BA, and BAB, whose concentrations depend on four binding constants:

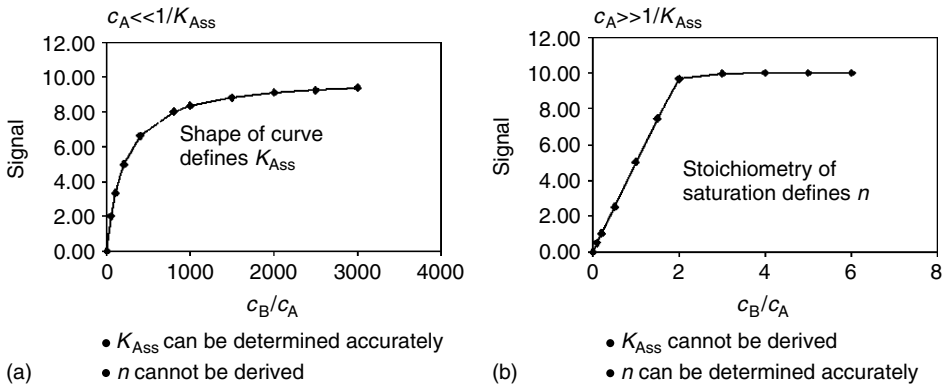

Fig. 5 Typical results of a normal and stoichiometric titration binding analysis.

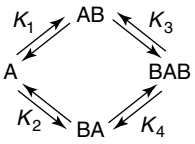

(21)

Under conditions where $c_{A,tot} \ll c_{B,tot}$, terms involving the total concentration of A do not occur in the analysis (as mentioned earlier), and it is therefore not possible to use Eq. (20) to analyze the stoichiometry of the binding equilibrium. However, even under these experimental conditions, it is possible to obtain information about the number of binding sites, provided the binding constants of the two processes are sufficiently different in magnitude.

Information about the minimum number of binding sites for B on the macromolecular species A can also be obtained if a signal can be measured, which specifically monitors the concentration of A fully saturated with B (BAB in our scheme). For example, the enzyme DNA polymerase has two binding sites for metal ions, and both need to be occupied for the enzyme to be active. If it is assumed that the two sites are independent, and hence $K_1 = K_4$ and $K_2 = K_3$ in Eq. (21), the following expression can be derived for the occupancy of the two sites (designated 1 & 2):

$$\theta_1 = \frac{c_{AB}}{c_{A,tot}} = \frac{c_B K_1}{1 + c_B K_1}$$

$$\theta_2 = \frac{c_{BA}}{c_{A,tot}} = \frac{c_B K_2}{1 + c_B K_2} \qquad (22)$$

and the proportion of A where both sites are occupied is given by:

$$\theta_{1,2} = \frac{c_{BAB}}{c_{A,tot}} = \theta_1 \theta_2$$

In the special case of identical binding sites ($K_{Ass,1} = K_{Ass,2}$), the dependence of $\theta_{1,2}$ on the total concentration of A ($c_{A,tot}$) is weakly sigmoidal at low concentrations of B, and not hyperbolic; this is a direct indication that A can bind more than one B. The total concentration of bound ligand ($= \theta_1 + \theta_2$) follows a hyperbolic dependence, as expected since the sites are independent.

3.6.3 Cooperative Binding

In the previous section, we discussed the case where the various binding sites were noninteracting; in this section we consider the other limiting case where A is either free, or fully occupied by B as the species AB_n, and the intermediate states $AB, AB_2, \ldots, AB_{n-2}$, and AB_{n-1} are not populated. This behavior arises because of positive interactions between the sites resulting in cooperative binding; according to Eq. (21), cooperative binding occurs when $K_3 \gg K_1$ and $K_4 \gg K_2$. The model considered here represents "all or none" behavior, which is not just a theoretical model but also one that does actually occur with biopolymers.

In cooperative binding following the "all or none" model

$$A + nB \rightleftharpoons AB_n$$

the association constant is defined by the expression:

$$K_{Ass}^{app} = \frac{c_{AB_n}}{c_A (c_B)^n}$$

Introducing the conservation condition for A with the further assumption that $c_{AB} \ll c_B$ yields the following equation:

$$\frac{c_{AB_n}}{c_{A,tot}} = \frac{(c_{B,tot})^n K_{Ass}^{app}}{1 + (c_{B,tot})^n K_{Ass}^{app}} \qquad (23)$$

This equation describes a sigmoidal binding curve, where the degree of sigmoidal behavior depends on the magnitude of n. The intrinsic binding constant

of B for A (K_{Ass}) can be determined from the apparent binding constant (K_{Ass}^{app}) using the following relationship:

$$K_{Ass}^{app} = (K_{Ass})^n$$

3.7 pH Dependence of Enzyme Catalyzed Reactions

The rate of an enzyme catalyzed reaction is not only dependent on the concentrations of enzyme and substrate, but also on the conditions of the reaction. An important parameter affecting rate is the pH, defined as $-\log_{10} c(H^+)$, and it is very common that enzymes have a pH optimum. The pH can have several effects: (1) protons may participate in the catalytic reaction itself; (2) the protonation state of substrates and cosubstrates may alter, with consequent effects on rate; (3) the protonation state of the enzyme itself may alter. In our example here, we deal with the last case. Proteins contain many groups that can undergo protonation–deprotonation reactions, including the N-terminal amino and C-terminal carboxyl groups, and the side chains of the following amino acids: Asp, Glu, His, Cys, Tyr, Lys, and Arg. Protonation/deprotonation reactions are examples of ligand binding equilibria, which are simplified by the experimental approach of using a buffered solution such that the concentration of H^+ in the solution remains constant throughout the experiment. The state of protonation of a group is conveniently represented by its pK_a value, which is the negative decadic logarithm of the dissociation constant for the protonation reaction:

$$K_a = \frac{c(H^+)c(A^-)}{c(HA)}$$

$$pK_a = -\log_{10} K_a$$

The proportions of a group A in the protonated $\theta(H)$ and deprotonated $\theta(-)$ states can be evaluated as follows:

$$\theta(-) = \frac{A^-}{A_{tot}} = \frac{K_a}{c(H^+) + K_a} = \frac{10^{-pK_a}}{10^{-pH} + 10^{-pK_a}}$$

$$\theta(H) = 1 - \theta(-) \qquad (24)$$

The following questions are important for analyzing the pH dependence of enzyme catalyzed reactions:

- how many protonation reactions participate?
- which protonation state must the pH-sensitive groups on the enzyme be in?
- what are the pK_a values of these groups?

We consider a general model to analyze the protonation equilibria. If the enzyme possesses n groups that can participate in protonation–deprotonation equilibria, then in principle 2^n different species can be formed. For example, if $n = 3$, all three groups can be protonated (HHH), two (HH–, H–H, and –HH), one (H–, –H–, and –H) or none (–). The probability (P) of occurrence of these species, and hence their relative concentrations, depends on the product of the probabilities that each individual group is in a particular state:

P(HHH) = P(group 1 is protonated)
× P(group 2 is protonated)
× P(group 3 is protonated)

P(HH–) = P(group 1 is protonated)
× P(group 2 is protonated)
× P(group 3 is unprotonated) and so on.

The probability of a group being in a particular protonation state is given by

Eq. (24), and combination of these probabilities multiplied by the total concentration of enzyme yields the concentrations of the different species.

The turnover rate is used as an "effect" or signal to monitor the protonation, and thus the observed rates can be used to analyze the thermodynamic protonation equilibria. In the general case, every species would be assigned an intensity factor, and the signal (observed rate of the reaction) would be the sum of all of these factors. For many analyses, one makes the simplifying assumption that only one species is catalytically active.

3.8 Pre-steady State Kinetics

Enzyme reactions proceed, in general, via several intermediate states. A simple model incorporating multiple states is shown below: enzyme and substrate associate to form an enzyme–substrate complex, which undergoes a conformational change to ES# before breaking down into enzyme and product.

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \underset{k_{-2}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES\#} \longrightarrow \mathrm{E} + \mathrm{P}$$

Since the concentrations of all the intermediate states are constant under steady state conditions, all of these states can, at least formally, be incorporated into a single kinetic intermediate state. It follows that under steady state conditions, kinetic data can provide no information about the existence and kinetic properties of intermediate enzyme–substrate complexes. An understanding of the mechanism of an enzyme catalyzed reaction needs information about these intermediate states, which is therefore usually obtained from kinetic studies before steady state has been established, usually by rapid reaction methods. Comprehensive coverage of the techniques and methods of analysis of pre-steady state kinetics is beyond the scope of this chapter, but we discuss here methods for analyzing simple exponential processes. Two approaches are used. In the first, the observed signal $S(t)$ is fitted to an exponential function of the following form:

$$S(t) = A\mathrm{e}^{-\mathrm{t}}/\tau, \text{ for decreasing signals.}$$
$$S(t) = A[1 - \mathrm{e}^{-\mathrm{t}/\tau}] \text{ for increasing signals.} \quad (25)$$

A is the amplitude of the reaction and τ the time constant, with the dimension of (time). If the kinetic mechanism of the observed process is known, then rate constants can be derived from the time constant. For example, for a simple dissociation process, the rate constant (k_{-1}) is given by $1/\tau$. In this case, the value of τ is independent of reactant concentration.

If both forward and back reactions can take place, then $1/\tau$ depends on both k_1 and k_{-1}. In the special case when the concentration of S is much greater than that of E, then the association rate constant is given by the equation $1/\tau = k_1 c_S + k_{-1}$. Values of the two rate constants can be determined from the dependence of τ on the substrate concentration c_S; a linear regression of $1/\tau$ versus c_S yields k_1 as the slope of the plot and k_{-1} as the y-intercept. For this analysis to be valid, it is important to be sure that the observed reaction represents a single exponential process. If the reaction involves more than one exponential phase, then more complex models need to be considered, since the minimal number of reaction steps is given by the number of exponential processes.

This method of analysis has several disadvantages, one of which is that intermediate parameters (τ) are evaluated from the data, which then form the basis for global fitting of the data; consequently, the global fitting is not carried out on the raw data directly. A second drawback is that the predictive power of this analysis as regards mechanism is rather limited.

A more powerful method for the analysis of such systems is to use direct integration of the differential equations that describe the mechanism of the reaction. An advantage of this procedure is that the fitting is carried out directly to the raw data. Since in most cases, particularly those of any kinetic complexity, the resulting systems of differential equations cannot be integrated analytically, numerical integration has to be used, which is not a problem in the currently given computer performance.

3.9 Association Kinetics Analyzed by Numerical Integration

The rate of a bimolecular association process $A + B \rightarrow AB$ is given by Eq. (26):

$$\frac{dc_{AB}}{dt} = k_1 c_A c_B \qquad (26)$$

The rate constants for bimolecular association reactions have dimensions $(\text{concentration})^{-1}\ (\text{time})^{-1}$. Although this differential equation has a very simple form, it does not have a very straightforward analytical solution. For this reason we use numerical integration methods to simulate theoretical data. This is a general approach that can be used to obtain solutions of complex kinetic processes. Although it is always easy to formulate differential equations like Eq. (26), which express the time dependence of the various concentrations, solving the equations is another matter; it is often impossible to obtain explicit analytical solutions of the form $c = f(t)$, from which concentrations of the reaction participants can be directly determined. What can, however, be evaluated is the concentration change (or "flux") for a species in a given time interval Δt under given conditions:

$$F_1 = k_1 c_A(t) c_B(t) \Delta t$$

The solution can be obtained by proceeding stepwise (using small values of Δt) and calculating $c_{AB}(t)$ using the expression:

$$c_{AB}(t + \Delta t) = c_{AB}(t) + F_1$$

This procedure is called *numerical integration*.

If we consider the following equilibrium:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES$$

There are two different fluxes:

$E + S \longrightarrow ES$, where $F_1 = k_1 c_E c_S \Delta t$

$ES \longrightarrow E + S$, where $F_{-1} = k_{-1} c_{ES} \Delta t$

The concentration changes are defined as follows:

$$\Delta c_E = -F_1 + F_{-1}$$

$$\Delta c_S = -F_1 + F_{-1}$$

$$\Delta c_{ES} = -F_{-1} + F_1$$

from which new concentrations can be derived using the following expression where, as before, $c_{i,\text{old}}$ is the old concentration of the species i before the new increment Δc_i:

$$c_i = c_{i,\text{old}} + \Delta c_i$$

3.10 Surface Binding Reactions

With the development and widespread use of the surface plasmon resonance (SPR) approach to study biomolecular interactions, analysis of binding reactions at surfaces is becoming increasingly important. Assuming that only one class of binding sites is present, one only has to consider that the surface has a certain binding capacity C. Since in a typical SPR experiment, the analyte is flushed along the surface in a continuous buffer flow, the concentration of analyte (c_A) available for binding is constant. Therefore, the flux (F_1) of the analyte to the surface is given by the following expression, where k_1 is the binding rate constant and Δt is the time increment used for numerical integration:

$$F_1 = k_1 c_A (C - c_{A,\text{bound}})\Delta t \qquad (27)$$

Release of bound analyte is given by a second flux, just as described in Eq. (27):

$$F_{-1} = k_{-1} c_{A,\text{bound}} \Delta t$$

3.11 Analysis of Competition Experiments

Competition experiments are widely used in the biosciences, particularly in studies of binding interactions. A simple example is shown in the following:

$$\text{AB} + \text{C} \overset{K_1}{\rightleftharpoons} \text{A} + \text{B} + \text{C} \overset{K_2}{\rightleftharpoons} \text{AC} + \text{B} \qquad (28)$$

In this example, the equilibrium between A, B, and AB is affected by the addition of C. The popularity of the competition technique is due to the fact that it can be used to investigate interactions (in this case the binding of A + C = AC) without having to detect the participating species (free C and the complex AC). The method relies on using one interaction (here A + B = AB) as a reporter to monitor the other. This assumes, of course, that a suitable signal is available to follow the formation of AB. Figure 6 illustrates the formation of AB, and the effect of adding C to a system containing A, B, and AB: on addition of C the species AC is formed at the expense of AB whose concentration falls, with a concomitant decrease in the observed signal.

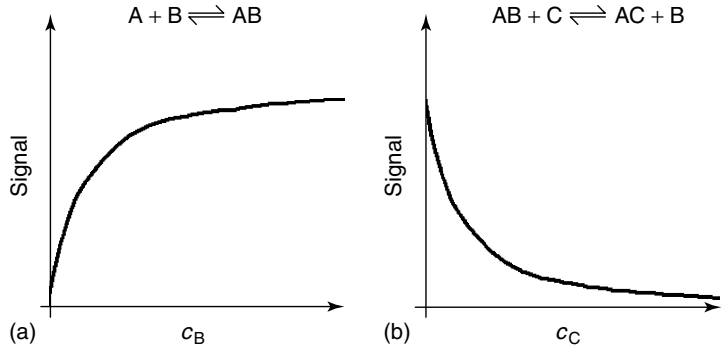

Fig. 6 Indirect analysis of molecular interaction of A and C by competition of the interaction of A with B.

It is also a desirable feature of competition experiments that they allow more precise comparison of the binding of different species (in this case B and C) to a common target (A) than is possible in separate binding experiments. It is also possible to use this approach with a single experimental set-up to test the binding of many different ligands to A, on the basis that all these ligands compete with B for the same binding site.

The analysis of coupled equilibria is the most complex problem that is considered in this chapter. It may seem surprising that such apparently straightforward systems like those shown in Eqs. (21) and (28) should present such great difficulties in analysis, the more so because it is a trivial matter to calculate the equilibrium constants, if the concentrations of the various species are known. However, that situation arises very rarely for several reasons:

- in most investigations, only some of the species can be detected;
- it is usually the case that only one "signal" is measured, whose dependence on the concentration of reaction participants may be complex, and must be derived from the model;
- experimental error.

Proceeding as we have done before with complex systems, we calculate theoretical data to deal with these systems. Since straightforward analytical solutions are not available, even for such simple cases as Eq. (28), numerical methods are used to simulate solutions of the equilibria. From an arbitrary initial state (e.g. only free A, B, and C present) we calculate for both isolated equilibria the final equilibrium concentrations, and the concentration changes needed to establish equilibrium. We then use these fluxes. Since, in every step, there are several fluxes, whose coupling is not taken into account, this approximate procedure takes us towards the equilibrium, but not directly to it. So the equilibrium has to be located iteratively.

We may write:

$$K_1 = \frac{c_{\mathrm{AB,Equil.}}}{c_{\mathrm{A,Equil.}} c_{\mathrm{B,Equil.}}}$$

or:

$$c_{\mathrm{AB,Equil.}} = K_1 c_{\mathrm{A,Equil.}} c_{\mathrm{B,Equil.}}$$

where, $c_{\mathrm{i,Equil.}}$ is the equilibrium concentration of i.

We are looking for the flux F, necessary to take us from the present concentrations to the equilibrium concentrations:

$$c_{\mathrm{AB,Equil.}} = c_{\mathrm{AB}} + F$$
$$c_{\mathrm{A,Equil.}} = c_{\mathrm{A}} - F$$
$$c_{\mathrm{B,Equil.}} = c_{\mathrm{B}} - F$$

Thus, we have:

$$(c_{\mathrm{AB}} + F) = K_1 (c_{\mathrm{A}} - F)(c_{\mathrm{B}} - F)$$

and

$$F^2 - \left(c_{\mathrm{A}} + c_{\mathrm{B}} + \frac{1}{K_1} \right) F + \frac{c_{\mathrm{A}} c_{\mathrm{B}} - c_{\mathrm{AB}}}{K_1} = 0$$

We calculate these fluxes for the two equilibria, and use these. We reach a new concentration state, which is not the true equilibrium state, since we have not taken the coupling of the equilibria into account. So the operation is repeated with newly calculated fluxes, and after ca. 50 iterations, we reach a stable equilibrium. The concentrations correspond to the joint equilibrium specified by the two thermodynamic association constants K_1 and K_2.

For practical applications, it is important that the calculated fluxes are not too large so that calculation does not overshoot the target. So, for example, if K_1 and K_2 are very large, and $c_A > c_B$ and $c_C > c_B$, our initial analysis of the first equilibrium will show that almost all of the B must flow to AB. At the same time, analysis of the second equilibrium will show that all of the B should flow to BC. When we take account of the two fluxes, we obtain negative concentrations in the first iteration. Since in this example, there are at most two fluxes for a single species (free B), this complication can be avoided by reducing every flux by 50%.

3.12 Regularization – Application to Analytical Ultracentrifugation

As outlined in the mathematical introduction (Sect 2.1), any model that describes an experiment can be used either as a discretely calculated function to describe an experiment or in a regularizing fashion to calculate the distribution of model parameters that best describe the experiment. In biochemistry, the latter approach was first applied to the analysis of relaxation kinetics or circular dichroism data. Here, we show how the approach can be used to analyze sedimentation velocity experiments in the analytical ultracentrifuge.

In an ultracentrifuge, dissolved macromolecules (e.g. proteins) are subjected to large gravitational fields, which causes them to sediment with a velocity that is described by the sedimentation coefficient s:

$$v = \frac{\mathrm{d}x}{\mathrm{d}t} = s\omega^2 x$$

where v is the velocity of the molecule, ω is the angular speed of the rotor, and x is the distance from the center of rotation. The sedimentation coefficient has the dimension of time and it is usually given in units of S (for Svedberg) with $1\ \mathrm{S} = 10^{-13}$ s. Larger molecules sediment faster and consequently have larger values of sedimentation coefficient than smaller ones. These differences in sedimentation can be exploited to detect interactions of macromolecules. In an analytical ultracentrifuge, the local concentration of particles in the centrifuge cell can be observed by optical absorption or refractive index measurements.

To illustrate such an experiment Fig. 7(a) shows the sedimentation of a mixture of two interacting proteins, N-acetylglutamate-kinase (NAGK) and the signal transducing protein PII from *Synechococcus* sp. PCC7942. NAGK is a hexamer with a molecular mass of 192 kg mol^{-1} and a sedimentation constant of 8 S, while PII is a tetramer with a molecular mass of 42 kg and sedimentation coefficient of 3 S. Two clearly separated boundaries can be observed, the faster sedimenting boundary (10 S) is formed by the complex of these two proteins while the slower one represents PII protein whose concentration in this experiment was chosen to be much larger than that of NAGK (Maheswaran et al. 2004). It is clear that the two boundaries are spread due to diffusion and that a straightforward analysis of the amounts of free and complex bound protein is difficult to estimate from the data directly. However, the movement of such boundaries in the analytical ultracentrifuge can be described using the Lamm equation derived by Lamm in 1929:

$$\frac{\partial c}{\partial t} = \frac{1}{x}\frac{\partial}{\partial x}\left[\frac{1}{x}\left(D\frac{\partial c}{\partial x} - s\omega^2 x^2\right)\right]$$

This equation can be solved by numerical methods and represents a model

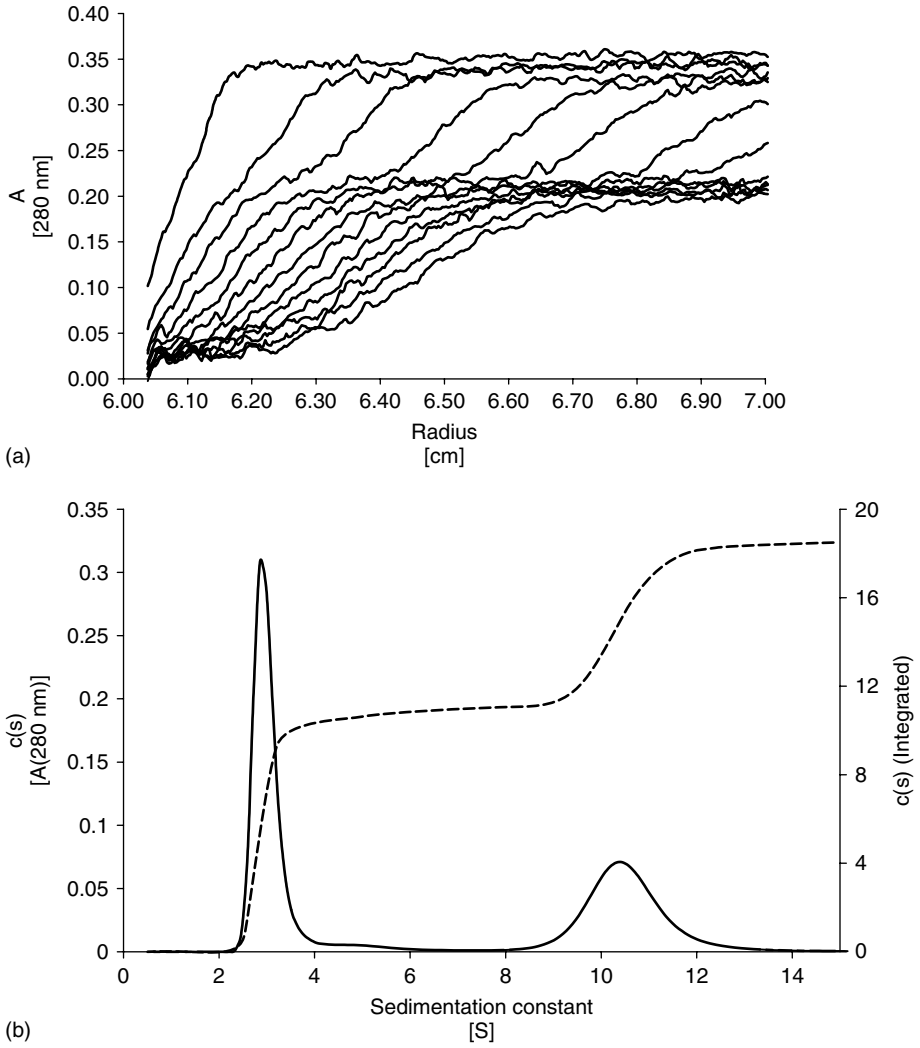

Fig. 7 Sedimentation of a mixture of 11.2 µM NAGK and 2.24 µM PII proteins (for details cf. text.) (a) Sedimentation profiles in the analytical ultracentrifuge taken every 19 min at a speed of 38 000 rpm. (b) Sedimentation coefficient distribution calculated with SEDFIT. The dotted line is the integral over the distribution and can be used to calculate the absorptions of free and bound proteins.

function of the type $c = f(x, t; s, D)$ where x and t are the independent variables and, s and D, the diffusion coefficient, are parameters that are constant throughout an experiment. Regularization algorithm given by Schuck in 2000 is similar to the following description using Lamm's differential equation. Thus, s and D are related to molecular parameters by the equations

$$s = \frac{M(1 - \bar{\nu}\sigma)}{N_A f} \text{ and } D = \frac{RT}{N_A f}$$

where M represents the molar mass (kg mol^{-1}), $\bar{\nu}$ the partial specific volume (m^3 kg^{-1}) and the f frictional coefficient (kg s^{-1}) of the particle; N_A and R are Avogadro's number and the gas constant, respectively. For a sphere of radius R_0, the frictional coefficient is given by Stokes law $f = 6 \cdot \pi \cdot \eta \cdot R_0$. Using $\bar{\nu}$ and the frictional ratio f/f_0, which is the ratio of the actual frictional coefficient of the particle to the frictional coefficient of a perfect sphere with the same volume, the diffusion coefficient can be related to the sedimentation coefficient by

$$D = \frac{RT}{6\pi\eta N_A}\sqrt[3]{\frac{2(1-\bar{\nu}\rho)}{9\bar{\nu}s\eta(f/f_0)^4}}$$

To analyze the sedimentation data using the regularizing procedure, we write the describing function in the form $\int c(s)f(x,t;s)\mathrm{d}s$ from which the sedimentation coefficient distribution $c(s)$ can be calculated from the original sedimentation data. The program to do this (SEDFIT) is available from Peter Schuck (http://www.analyticalultracentrifugation.com/default.htm).

Figure 7(b) shows the sedimentation profiles represented as the sedimentation coefficient distribution and from the integral of the two peaks the absorption and thus relative amounts of free and bound protein can be evaluated; from this it was calculated that the proteins form a 1 : 1 (NAGK hexamer: PII trimer) complex.

Bibliography

The present text is a modified and expanded version of Chapter 9 published in Pingoud, A., Urbanke, C., Hoggett, J. & Jeltsch, A. (2002) Biochemical Methods, Wiley-VCH. In that book, detailed step-by-step instructions can be found on how to implement many of the procedures described here in Excel worksheets.

Keywords

Autoradiography
The detection of radioactivity using photographic emulsions.

Fluorography
A sensitive form of autoradiography in which radioactivity is detected by light emanating from a scintillator (or ''fluor'') in close contact with the sample.

Half-life
The time taken for the activity of a radionuclide to lose half its value by decay.

Quenching
Any process that reduces the efficiency of detection of radioactivity.

Radioactivity
The emission of ionizing radiations by matter.

Radioisotopes
Atoms with the same atomic number (protons) but differing mass numbers (protons plus neutrons), and having unstable nuclei that decay to a stable state by the emission of ionizing radiations; for example, ^{14}C is a radioisotope of ^{12}C.

Radionuclide
An atomic species that is radioactive, for example, ^{3}H, ^{14}C and so on.

Specific Activity
The rate of decay per unit mass, for example dpm g^{-1}, Ci $mole^{-1}$, Bq $mmol^{-1}$.

Radioisotopes are used extensively in molecular biology. They can be incorporated into DNA, RNA, and protein molecules, both *in vivo* and *in vitro*. As a consequence, the presence or metabolism of macromolecules can be investigated or ''traced.'' The incorporation of radioisotopes allows the detection of minute quantities, thereby facilitating experimental techniques that require high sensitivity. Labeling *in vitro* is much more efficient than labeling *in vivo*; specific activities regularly reach 10^{8}–10^{9} dpm μ g^{-1} for *in vitro* ^{32}P–labeling of DNA, for example. High-specific activity leads to greater sensitivity. Specific activity is inversely related to the half-life of the radioisotope. Low-energy emitters, such as ^{3}H and ^{35}S provide high resolution in autoradiography. High-energy, high-specific activity emitters such as ^{32}P for nucleic acid labeling, provide great sensitivity but low resolution in autoradiography. The radionuclides ^{3}H, ^{14}C, ^{35}S, and ^{125}I are most commonly used for protein labeling; ^{32}P and ^{33}P are most commonly used for nucleic acid labeling.

1 Principles

1.1 Radioactive Decay

Atomic nuclei contain a number of protons (referred to as the atomic number, Z) and, except in the case of hydrogen, neutrons (N) also. The total number of these nuclear atomic particles (or nucleons) is the mass number (A), that is $A = Z + N$. The atomic number determines the element (e.g. when $Z = 6$ the element is carbon). Isotopes are elements that have the same atomic number but differing mass numbers. For example, ^{12}C and ^{14}C are different isotopes of carbon, both with atomic number 6, but differing mass numbers, 12 and 14 respectively, thereby indicating that the isotopes have either 6 or 8 neutrons. Some atoms are unstable: they have the incorrect number of neutrons for nuclear stability and are referred to as radionuclides or, more commonly, radioisotopes. Radioactivity is the means by which unstable atoms reach a stable state. The process can occur in one step, as is the case with most radioisotopes used in biological experiments, or in a number of steps, such as in the case of uranium, which decays through several radionuclides to a stable isotope of lead. There are many ways in which this decay can occur.

Alpha decay is loss of a helium nucleus, $^{4}_{2}He$, for example:

$$^{226}_{88}Ra \longrightarrow {}^{222}_{86}Rn + {}^{4}_{2}He$$

Alpha particles are heavy and slow moving, have poor penetration (3–9 cm), and a net double positive charge. Alpha emitters are found mostly amongst the heavier elements and are rarely used by biologists.

Beta decay results from the conversion of a neutron to a proton (negatron emission) or a proton to a neutron (positron emission). Of most relevance to biologists is the negatron emission form of β decay, involving the loss of an electron, which forms the ionizing radiation. Many commonly used radionuclides decay by this mechanism (e.g. ^{3}H, ^{14}C, ^{35}S, ^{33}P, ^{32}P). For example, ^{14}C decays as follows:

$$^{14}_{6}C \longrightarrow {}^{14}_{7}N + \beta^{-}$$

Beta particles are less charged, lighter, and faster moving than alpha particles; their energy and therefore the range of the radiation produced, varies with the source. This has significant implications for their use and safe handling, and this is discussed later (Sect. 2).

Gamma decay is the emission of electromagnetic radiation, with properties identical to X rays. It often accompanies β-decay. For example:

$$^{131}_{63}I \longrightarrow {}^{131}_{64}Xe + \beta^{-} + \gamma$$

Electron capture is a process by which a proton is combined with an electron from the innermost K shell, forming a neutron; following a complex series of events, an X ray is emitted. An example of this kind of decay is shown by ^{125}I:

$$^{125}_{53}I \longrightarrow {}^{125}_{52}Te + \text{X ray}$$

Decay of ^{125}I is also accompanied by emission of Auger electrons, radiation of low energy, providing high-resolution detection in autoradiography (see Sect. 3).

1.2 Kinetics of Decay

It is impossible to predict when an individual unstable nucleus will decay,

but when observing the decay of a large number of unstable atoms there is a statistical probability that a certain number will decay within a given time. The number that decay per unit time is proportional to the number of unstable atoms present. Mathematically this is represented as:

$$\frac{-\mathrm{d}N}{\mathrm{d}t}\alpha N \quad \text{or} \quad \frac{-\mathrm{d}N}{\mathrm{d}t} = \lambda N \qquad (1)$$

where N = number of unstable nuclei, t = time and λ = the decay constant sec^{-1}. Therefore the amount of radioactivity (A, the count rate) is:

$$A = \frac{\mathrm{d}N}{\mathrm{d}t} = \lambda N \qquad (2)$$

As a consequence, radioisotopes exhibit exponential decay as is illustrated by the graphs in Fig. 1, the rate at which a radioisotope decays being determined by its decay constant, λ. This constant is a fundamental property of a radioisotope, and is not influenced by temperature, pressure, and so on. Integration of Eq. (1) with respect to time (letting $N = N_0$ at $t = 0$) gives the following expression:

$$N = N_0 \mathrm{e}^{-\lambda t} \qquad (3)$$

and

$$1\mathrm{n}\frac{Nt}{N_0} = -\lambda t \qquad (4)$$

(where $N = Nt$ at time t)

or:

$$1\mathrm{n}\ \text{count rate(time, } t_2) = 1\mathrm{n}\ \text{count rate(time, } t_l) - \lambda t \qquad (5)$$

Thus, if the decay constant is known, the count rate at any time can be calculated from a known count rate and time. In practice, decay constants are rarely quoted;

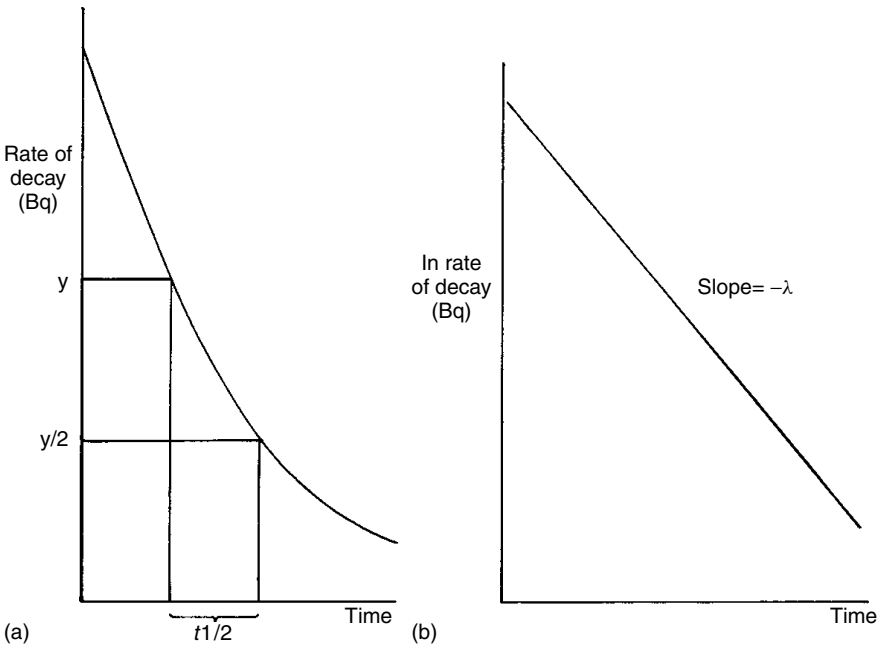

Fig. 1 The rate of decay with time on a linear (a) and semilogarithmic (b) scale.

half-life ($t_{1/2}$) is in many ways a more convenient way to express decay kinetics. The half-life is the time taken for the count rate to drop to half of a given value, and is depicted in Fig. 1.

From Eq. (4), letting $N_t = (1/2)N_0$:

$$1n\tfrac{1}{2} = -\lambda t_{1/2}$$

or

$$1n\ 2 = \lambda t_{1/2} \tag{6}$$

or

$$\lambda = \frac{0.693}{t_{1/2}} \tag{7}$$

So, if the half-life is known, a combination of Eqs. (7 and 5) can be used to determine future or past levels of radioactivity. This is particularly valuable when working with short half-life radioisotopes such as ^{32}P. Decay tables based on this type of mathematics are available in the reference literature and suppliers' catalogues.

1.3 Units

The International System of Units (SI System) uses the becquerel (Bq) as the unit of radioactivity, lBq being one disintegration per second (1d.p.s.). However, a frequently used unit is the curie (Ci). This unit originates from the number of disintegrations from a gram of pure radium: 1 Ci, therefore, being 3.7×10^{10} d.p.s. (or 37 GBq). This is a very large amount of radioactivity, and most molecular biologists use quantities measured in microcuries (μCi); 1 μCi is 2.22×10^6 d.p.m. (disintegrations per minute) or 37 kBq. The becquerel is the internationally recognized unit of radioactivity and has been adopted by the International Commission for Radiological Protection (ICRP). As a consequence, most countries have incorporated the unit into their legislation regarding use and disposal of radioactivity; suppliers of radioisotopes, however, frequently still use the Ci for historical reasons.

The units Bq, Ci, d.p.s., and d.p.m. all refer to the actual number of nuclear disintegrations. The rate of decay detected by an instrument is measured in counts per minute (c.p.m.). This is usually less than the true rate, d.p.m., because counting is rarely 100% efficient. Consequently, it is normal practice to calibrate the detector and calculate d.p.m. as c.p.m. × 100/efficiency, as a percentage value. Surprisingly, it is sometimes possible for the recorded count rate (c.p.m.) to exceed the actual rate of decay. This can occur in liquid scintillation counters and is discussed in Sect. 6.2.

The term *specific activity* is important in relation to experiments with radioactivity. The term refers to the amount of radioactivity per unit mass; thus d.p.m. g^{-1}, c.p.m. g^{-1}, Ci $mole^{-1}$, Bq $mole^{-1}$ are all units of specific activity. Frequently, molecular biologists require the highest specific activity possible; for example, DNA labeling with high-specific activity ^{32}P-labeled nucleotides results in probes with the maximum possible sensitivity. The highest specific activities are obtained from radioisotopes with the shortest half-lives (see Sect. 3). Sometimes it is necessary or desirable to change the specific activity by addition of nonradioactive material (a "cold" carrier). This can be achieved by applying the following formula:

$$W = Ma\left(\frac{1}{A'} - \frac{1}{A}\right) \tag{8}$$

where W = mass of cold carrier required, expressed in mg; a = amount of radioactivity present, expressed in MBq; M = molecular weight of the compound; A = the original specific activity MBq $mmol^{-1}$;

Tab. 1 A summary of units and their definitions.

Unit	*Abbreviation*	*Definition*
Counts per minute or second	c.p.m. c.p.s.	The recorded rate of decay
Disintegration per minute or second	d.p.m. d.p.s.	The actual rate of decay
Curie	Ci	The number of d.p.s. equivalent to 1 g of radium (3.7×10^{10} d.p.s.)
Millicurie	mCi	Ci $\times 10^{-3}$ or 2.22×10^9 d.p.m.
Microcurie	mCi	Ci $\times 10^{-6}$ or 2.22×10^6 d.p.m.
Becquerel (SI Unit)	Bq	1 d.p.s.
Gigabecquerel (SI Unit)	GBq	10^9 Bq or 27.027 mCi
Megabecquerel (SI Unit)	MBq	10^6 Bq or 27.027 μCi
Electron volt	eV	The energy attained by an electron accelerated through a potential difference of 1 V. Equivalent to 1.6×10^{-19} joules.
Roentgen	R	The amount of radiation, which produces 1.61×10^{15} ion pairs per kg of air (2.58×10^{-4} coulombs kg^{-1})
Rad	rad	That dose which gives an energy absorption of 0.01 joule kg^{-1} (J kg^{-1})
Gray (SI Unit)	Gy	That dose which gives an energy absorption of 1 joule kg^{-1}. Thus, 1 Gy = 100 rad.
Rem	rem	That amount of radiation which gives a dose in human equivalent to 1 rad of X rays.
Sievert	Sv	That amount of radiation, which gives a dose in human equivalent to 1 gray of X rays. Thus, 1 Sv = 100 rem.

A' = the required specific activity MBq $mmol^{-1}$.

Units and definitions are summarized in Table 1.

2 Radiation Protection

2.1 General Principles

Toxicity is the greatest practical disadvantage of using radioisotopes. They produce ionizing radiations, which, when absorbed by cells, cause ionization and the production of free radicals. These radicals, in turn, cause mutation of DNA, hydrolysis of proteins, and ultimately cell death. The toxicity of radiation is dependent not simply on the amount present but on the amount absorbed, the energy of the radiation and its nature, and therefore the biological effect. The international unit to describe absorbed dose, taking into account its biological effectiveness, is the sievert (Sv), known as the equivalent dose. This is calculated from the absorbed dose (gray, Gy), which is a measure of the energy absorbed per unit mass (joule kg^{-1}), multiplied by a radiation-weighting factor (W_R). For X rays, γ-rays and ß-radiations this

weighting factor is one, that is the equivalent dose = absorbed dose = joule kg^{-1}. Other forms of radiation such as neutrons and α-particles are more toxic, with a W_R of up to 20.

Radiation is emitted from a source in all directions, so the level of irradiation, and therefore the dose, is inversely related to the square of the distance from the source. A commonly used parameter is dose rate (Sv per minute or hour, etc.). If this is known, either from quoted figures or measurements with a dose rate meter, total doses can be calculated. For example, if a source is delivering lmSv per hour and you work with the source for 15 min the dose will be 250 μSv. To calculate dose rates at any distance, use the formula:

$$\text{Dose rate}_1 \times \text{distance}_1^2 = \text{dose rate}_2 \times \text{distance}_2^2 \quad (9)$$

There are official dose limits for workers using radiation: 20 mSv $year^{-1}$ for the whole body. To put this in perspective, it represents about 10 times the background radiation. There are also annual dose limits for specific organs, for example, 150 mSv for the lens of the eye, and 500 mSv for the hand; however, a fundamental principle behind radiation protection is that doses must be as low as reasonably practical (the ALARP principle). In practice this means that workers should not work up to a dose limit, but rather always strive to reduce their exposure. For example, radioisotopes should only be used if there is a net benefit (see the end of Sect. 6.4); and when radioisotopes are used, all practical steps must be taken to reduce dose to workers, (for example, by choosing a low-energy emitter).

So far the discussion has been primarily concerned with *external radiation*, that is, radioisotopes outside the body. However, a potential hazard in working with radioisotopes in a biology laboratory is via *internal radiation*: radiation that has entered the body by, for example, ingestion or inhalation. The annual limit on intake (ALI) provides a guide to relevant dosimetry. ALIs for radioisotopes used in molecular biology are included in Table 2, but it should be noted that the figures are for the elemental isotopes, and not particular formulations. The ALI for ^{3}H-thymidine is lower, for example, than that for ^3H_2O, because it is more toxic due to its longer clearance time from the body. Exhaustive lists of ALI can be found in the detailed radiation protection literature.

The various radioisotopes used in molecular biology fall into two broad categories of hazard: those that present an external radiation hazard (^{32}P and ^{125}I) and those that present only a negligible (^{14}C, ^{35}S, ^{33}P) or zero (^{3}H) external radiation risk. Clearly, therefore, it is incumbent on the laboratory worker to avoid ^{32}P or ^{125}I wherever possible. All radioisotopes present an internal radiation risk, particularly when handled as liquids or gases, but again, the penetrating, higher energy radiations such as from ^{32}P and ^{125}I present the greatest risk. The figures for annual limit on intake shown in Table 2 give an indication of the relative risk from ingestion. Shielding, other than that routinely used for storage, is not usually required for ^{14}C, ^{35}S, ^{33}P or ^{3}H when used at the levels appropriate for most molecular biology experiments. Here the potential risk is through ingestion, which can be avoided by adherence to good laboratory protocols that are generally applicable to work with all radionuclides: wearing of laboratory coat, gloves, and safety spectacles, working in spill trays lined with absorbent paper, double containment of stocks for storage

Tab. 2 Properties and radiation protection data of radioisotopes commonly used in the molecular biological sciences. Radioisotopes vary considerably with respect to their properties and potential hazards. The table below summarizes some generally useful information about isotopes used in biological experiments.

	Isotope						
Property/radiation protection criteria	^{3}H	^{14}C	^{35}S	^{33}P	^{32}P	^{125}I	^{131}I
$t_{1/2}$	12.3 years	5730 years	87.4 days	25.4 days	14.3 days	59.6 days	8.04 days
Mode of decay	β^-	β^-	β^-	β^-	β^-	X (EC)	γ and β
Max β energy (MeV)	0.019	0.156	0.167	0.249	1.709	Auger electrons	0.806
Monitor	Swabs counted by liquid scintillation	β-counter	β-counter	β-counter	β-counter	γ-probe	β-counter
Biological monitoring	Urine	Urine, breath	Urine	Urine	Urine	Thyroid	Thyroid
ALI[a]	480[b]	34	15	14	6.3	1.3[c]	0.9[c]
Critical organ	Whole body	Whole body/fat	Whole body/testis	Bone	Bone	Thyroid	Thyroid
Maximum range in air	6 mm	24 cm	26 cm	49 cm	790 cm	>10 m	>10 m
Shielding required	None	Perspex 1 cm	Perspex 1 cm	Perspex 1 cm	Perspex 1 cm	Lead 0.25 mm or lead	Lead 13 mm
γ dose rate (μSv h^{-1} from 1GBq at 1 m	–	–	–	–	(β-dose rate 210 mSv at surface of 1 MBq ml^{-1}	34	51
Special considerations	Monitoring difficulties lead to potential internal hazard. DNA precursors more toxic than tritiated water.	Avoid generation of CO_2	Avoid generation of SO_2		Potential high source of external radiation. Lead shielding and finger dosimeters for quantities greater than 300 and 30 MBq respectively.	Iodine sublimes, work in fume hood. Spills should be treated with sodium thiosulphate solution prior to decontamination. Iodine compounds may penetrate rubber gloves – wear two pairs.	

[a]Based on a dose limit of 20 mSv using the most restrictive dose coefficients for inhalation or ingestion; some figures differ in Germany.
[b]Organically bound H-3.
[c]Based on dose equivalent limit of 500 mSv to thyroid.

and transport, regular and routine monitoring, no eating and drinking (or sucking pencils etc.), in the laboratory, no mouth pipetting, clear delineation of areas used for radioisotope work and washing hands when leaving the laboratory.

Dose rates from λ sources are quoted as the specific dose rate constant. For ^{125}I, this figure is 3.4×10^{-2} μSv h^{-1} MBq^{-1} at 1 m.

For ^{32}P the following formula can be used:

$$\text{dose rate}(\mu\text{Sv h}^{-1})\text{at 30 cm} = 54 \times \text{activity (MBq)} \quad (10)$$

Using Eqs. (9 and 10), a 1 MBq source of ^{32}P (approx 27 μCi) has a dose rate of 0.9 μSv min^{-1} at 30 cm and 0.81 Sv min^{-1} at 1 cm.

Clearly, shielding is required for work with ^{32}P and ^{125}I; the most practical is 1 cm acrylic for ^{32}P and 1 cm lead-impregnated acrylic for ^{125}I. High-energy β-emitters generate secondary X rays from absorbers, known as bremsstrahlung radiation. The generation of this radiation increases with the atomic weight of the absorber. Hence lead-impregnated acrylic can generate bremsstrahlung radiation, and is therefore not ideally suited for use with ^{32}P.

Vials or test tubes containing ^{32}P or ^{125}I must not be handled directly even when using a body shield, as doses can potentially be very high. They must be manipulated with forceps or some other appropriate device, or kept in acrylic holders such as those specifically marketed by radioisotope and radiation protection equipment suppliers. Automatic pipettes should carry small acrylic shields. Workers who frequently use ^{32}P may be advised to wear fingertip and body dosemeters. In all cases, the member of the staff who is responsible for radiation protection (e.g. Radiation Protection Supervisor or Radiation Protection Advisor) should be consulted. He/she will advise on the laboratory requirements and the type of laboratory required. In the United Kingdom, this is most likely to be a ''Supervised Laboratory'' (i.e. one in which it is theoretically possible to exceed 1/10 but not more than 3/10 of the recommended dose limit). When dealing with penetrating radiations, remember the basic rules of radiation protection:

maximize distance
minimize time of exposure
use shielding

Do dose estimates on your experiments using the formula described above (Eqs. 9 and 10) and the data in Table 2. Monitor regularly. A sensible precaution when using radioactivity in a protocol for the first time is to do a dummy run with ink in place of the radioisotope solution. A further simple precaution is to always add radioisotopes to mixtures last where possible; this reduces the time of exposure and risk of contamination.

2.2 Unpacking and Dispensing Radioactive Solutions

The following advice applies to unpacking and dispensing solutions emitting penetrating radiations such as from ^{32}P or ^{125}I.

1. Study the data sheet supplied with the radioisotope, do all necessary calculations (including dose assessment on the unpacking and dispensing procedure) and prepare a receptacle containing nonradioactive carrier as necessary, securely attach a label to this receptacle

that states your name, date, radionuclide and radioactive concentration. Manipulation of the stock radioactive solution should be carried out only when everything else is ready.
2. Wear laboratory coat, personal dosimeters (body and fingertip, see Sect. 6.5) safety spectacles, one or two pairs of disposable gloves, lay out all your equipment behind a body screen in a lined spill tray ensuring that no receptacles for liquids can be knocked over. Switch on a monitor and check the battery.
3. Open the sealed container, wipe test the interior with a piece of tissue paper held by forceps, and check the paper against the monitor. Regularly repeat this wipe test throughout the procedure to check for contamination outside the sample vial.
4. Remove lid of inner container surrounding the sample vial. Wipe test the top of the vial. Dispense sample without removing vial if possible; alternatively, if necessary, transfer the inner vial, with forceps, to an acrylic holder.
5. If dispensing with a syringe through a Teflon seal, insert a second needle in the seal as an air bleed. Surround the needle on the syringe with tissue to absorb any tiny drops of contamination. Handle the syringe for as short a time as possible but without reducing dexterity.
6. If dispensing with an automatic pipette, remove lid or seal with care and use an acrylic pipette shield.
7. Place contaminated tissues in a shielded container, rinse syringe/pipette tips in detergent solution for aqueous disposal (this minimizes the radioactivity in solid waste), and place disposable syringe or pipette tip in an appropriate shielded waste disposal container.
8. Repack the stock container, and wipe test all surfaces.
9. Monitor gloves, cuffs, all working surfaces, forceps and so on. Return stock to storage area. Upon completion of work remove laboratory coat, wash and monitor hands, and complete all necessary records in the radioisotope log.

If you are dispensing low-energy radioisotopes, it may be unrealistic to apply all aspects of the above procedure: ^{3}H for example, is not detected by bench monitors and the risk from external radiation is negligible, and therefore shielding is not required. However, the same **principles** apply, in that the risk of contamination should be reduced wherever possible, by, for example, working in a spill tray and preparing everything prior to dispensing the radioisotope.

3 The Choice of Radionuclide

The relative order of increasing radiation hazard is: ^{3}H, ^{14}C, ^{35}S, ^{33}P, ^{32}P, ^{131}I, and ^{125}I. Choose the radioisotope with lowest toxicity where possible. Remember that the shorter the half-life the greater the potential specific activity. The high-energy emitters give high counting efficiencies and strong signals in autoradiography. The lower-energy emitters give lower detection efficiencies but high resolution in autoradiography. The relative merits of radionuclides used in molecular biology are provided in Table 3. As a consequence, ^{32}P provides the highest sensitivity for labeling of probes and filter hybridization for genomic southern blots and northern analysis; ^{35}S and ^{33}P are preferred for DNA sequencing, and ^{35}S and ^{3}H are preferred for *in situ* hybridization and detection of unscheduled DNA synthesis. Phosphorus-33 is a good compromise for most DNA experiments as it combines the features of

Tab. 3 The relative merits of commonly used radionuclides.

	Advantages	*Disadvantages*
^{3}H	Safety High specific activity Wide choice of labeling position in organic compounds High resolution in autoradiography	Low efficiency of detection ^{3}H is large compared with ^{1}H and may cause an isotope effect Isotope exchange with the environment
^{14}C	Safety Wide choice of labeling position in organic compounds High resolution in autoradiography	Low specific activity significantly reduces value in molecular biology
^{35}S	High specific activity Good resolution in autoradiography	Relatively long biological half-life
^{33}P	High specific activity Safety relative to ^{32}P Longer half-life than ^{32}P Good resolution in autoradiography	Short half-life relative to ^{35}S Cost
^{32}P	Sensitivity of detection (10 fg or 50 dpm cm^{-2} in filter hybridization) Short half-life simplified disposal High specific activity Cerenkov counting	Short half-life effects cost and experimental design External radiation hazard Poor resolution in autoradiography
^{125}I	Ease of detection High specific activity Efficient *in vitro* labeling of proteins	Safety: radiation is penetrating and ^{125}I accumulates in thyroid, ALI is very low

relatively high-specific activity, and lower toxicity than ^{32}P.

4 Nucleic Acid Labeling

Radiolabels are most commonly introduced into nucleic acids by addition of single- or multiple-labeled nucleotides using enzyme-catalyzed reactions (Table 4 and Figs. 2 and 3). Most DNA and RNA polymerases are specific for particular pre-existing nucleic acid templates (e.g. DNA-dependent RNA polymerase) and synthesize a polynucleotide complementary to that template. There are two polymerization reactions that do not create polynucleotides complementary to a template: those catalyzed by terminal deoxynucleotidyl transferase from calf intestine, which adds deoxynucleotides to a 3′ end of DNA or RNA; and poly (A) polymerase, which adds adenosine monophosphates to 3′ ends of RNA molecules. All DNA polymerases require a nucleotide with a free 3′-hydroxyl hydrogen bonded to the template (i.e. a primer). RNA polymerases require a promoter, a specific DNA sequence on a double stranded-DNA molecule, in order to initiate transcription (RNA synthesis).

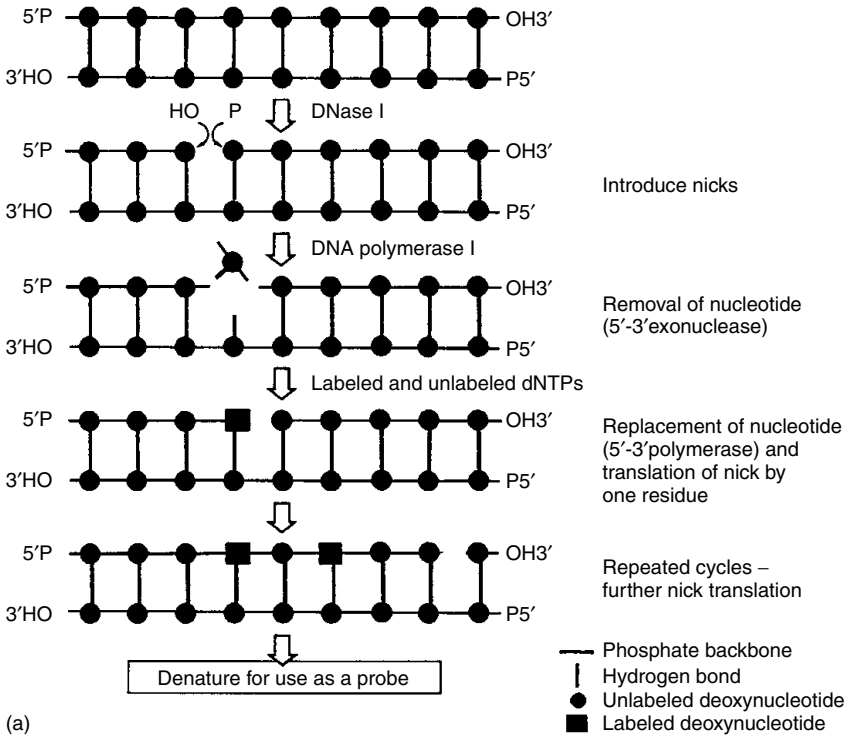

Fig. 2 Some methods for *in vitro* labeling of DNA are as follows: (a) the nick-translation reaction; (b) the random primer labeling reaction; (c) the 5′-end-labeling reaction using T4 polynucleotide kinase; (d) the 3′-end-labeling reaction using terminal deoxynucleotidyl transferase; (e) in-filling reaction using Klenow polymerase. (Reprinted with permission from Oxford University Press.)

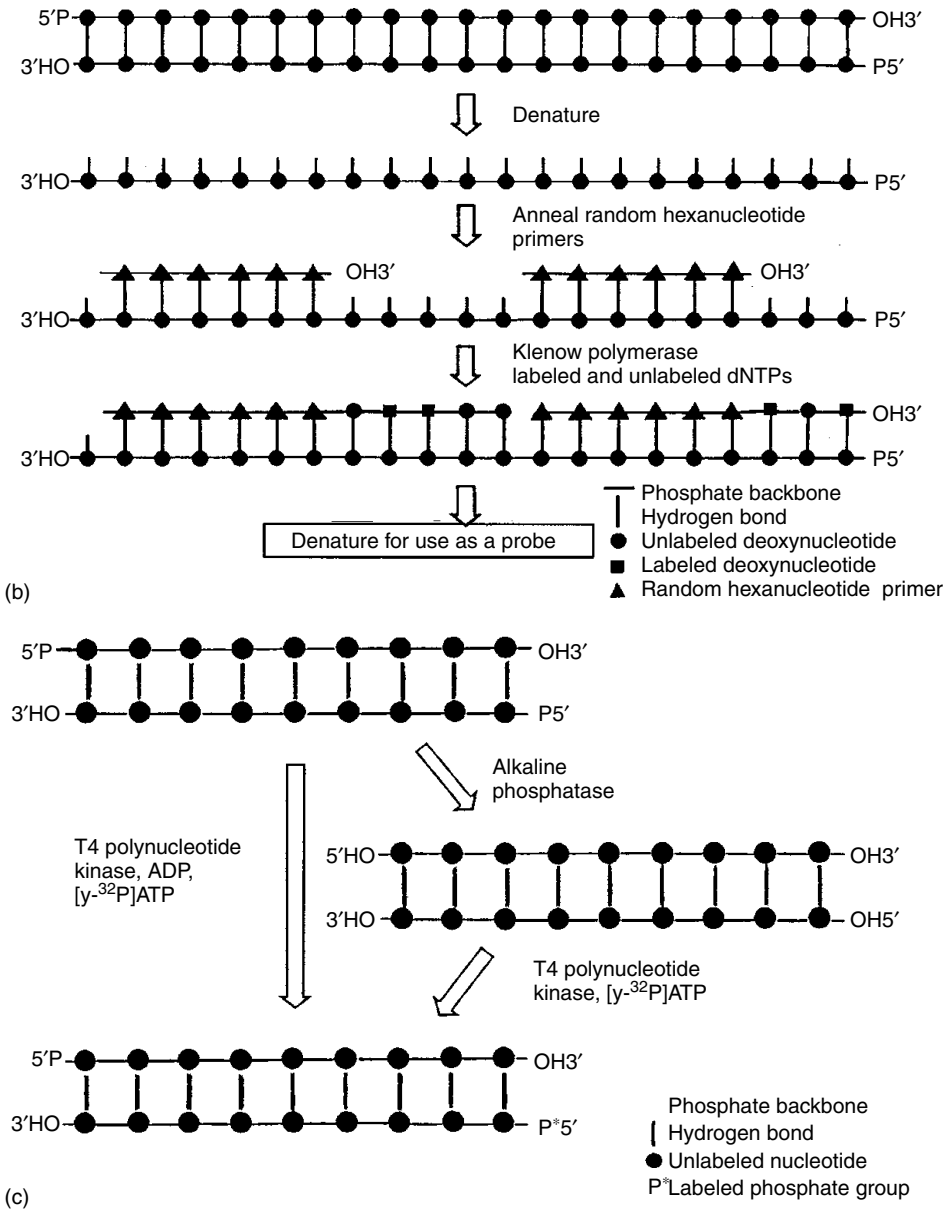

Fig. 2 (*Continued*)

Modification reactions can be used to incorporate labeling, for example, the addition of a ^{32}P phosphate to the 5′-end of a nucleic acid molecule by the enzyme T4 polynucleotide kinase using [^{32}P-γ] ATP as substrate.

When a labeling reaction is complete it is necessary to estimate the extent of

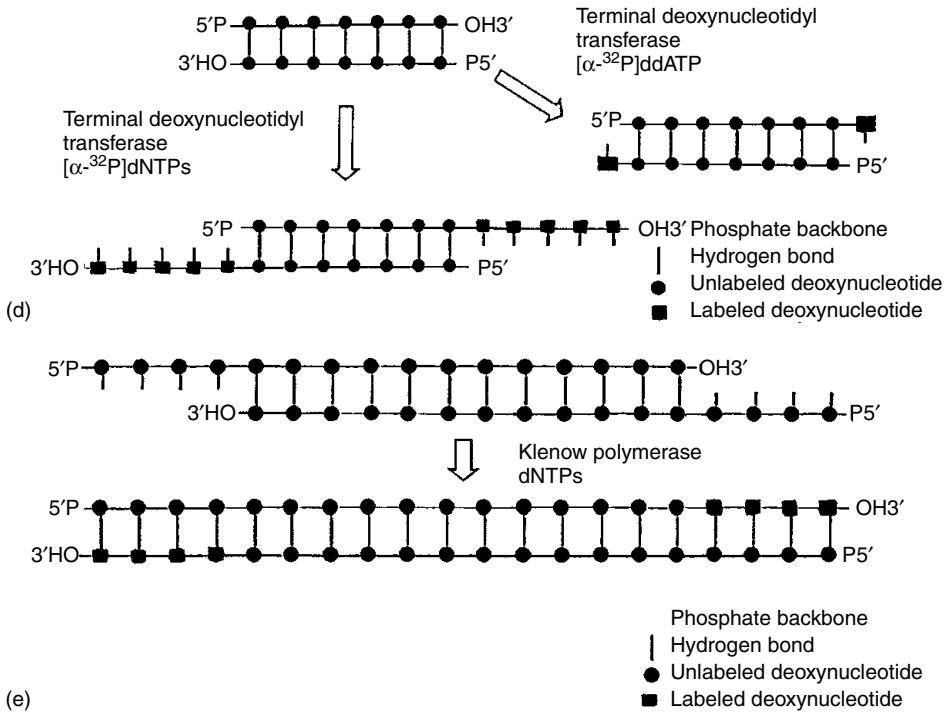

Fig. 2 (*Continued*)

incorporation. To do this, a small aliquot (2 µl) is removed from the reaction and diluted to a known volume (say 20 µl) with water. Two aliquots of this are counted in a scintillation counter. Two further aliquots are transferred to small tubes containing a few µg of carrier DNA or RNA in solution. The tubes are then filled with 10% trichloroacetic acid solution and left on ice for 30 min. The nucleic acids precipitate and can be collected on glass fiber filters. These are also counted in a scintillation counter. Comparison of these counts with the unprecipitated samples gives an indication of the percentage of incorporation, which should be at least 50% for most labeling protocols.

It is not always necessary to remove free, unincorporated labeled nucleotides from labeled probes; but if it is thought to be necessary, free label can be removed by ethanol precipitation of the probe in the presence of 0.1 M ammonium acetate or by the use of a 'spin column': Sephadex G25 swollen in buffer in a disposable syringe or pipette tip plugged with siliconized glass wool. The sample is applied to the column and, following centrifugation, the labeled probe is recovered from the centrifuge tube. Free label remains in the column. Alternatively, commercially made kits for purification of nucleic acids can be used, but these are usually more expensive.

5 Protein Labeling

Proteins are most frequently radiolabeled with ^{3}H, ^{14}C, ^{35}S, or ^{125}I. Tritium and

Tab. 4 Properties of nucleic acid–labeling reactions.

Method	*Labeling density*	*Template*	*Amount of template (typical)*	*Reaction time*	*Incorporation efficiency*	*Nature of probe*	*Amount of probe*	*Specific activity of probe (dpm μg^{-1})*
Random prime	Uniform	ssDNA (and denatured dsDNA)	25 ng	5 min–3 h	~75%	DNA	40–50 ng	5×10^9
Nick translation	Uniform	dsDNA	0.5–1 μg	~2 h	~60%	DNA	0.5–1 μg	5×10^8
Transcription labeling	Uniform	dsDNA	0.5–1 μg	1 h	~75%	RNA	~250 ng	5×10^9
3′-end labeling	End	Oligo or DNA fragment	~10 pmol ends	30–60 min	Variable	Oligo or DNA	10 pmols	5×10^6
End repair	End	Oligo or dsDNA fragment	~100 pmols ends	15 min	Variable	Oligo or DNA	100 pmols	5×10^5
5′-end labeling	End	Oligo or DNA fragment (dephosphorylated for forward reaction)	~10 pmol ends	~1 h	Variable	Oligo or DNA	10 pmols	5×10^6

^{14}C are used for reasons of safety and practicality (because of their long half-life) whenever it is not essential to have proteins labeled to high-specific activity. Proteins can be labeled *in vivo* by incubating cells with labeled amino-acids. Alternatively they can be labeled *in vitro* with N-succinimidyl [2,3–^{3}H] propionate or by reductive methylation with [^{14}C] formaldehyde. Both techniques normally result in

proteins that retain their biological activity. Methionine labeled with ^{35}S is used for *in vivo* labeling and *in vitro* protein synthesis as it provides a higher specific activity and good resolution in autoradiography of polyacrylamide gels used for analysis of products.

Radioiodination is used when proteins with a high-specific activity are required, for example, in radioimmunoassay and related techniques. Activities of up to 10^8 dpm μg^{-1} can be achieved. There are many methods that rely on either direct oxidative iodination or indirect conjugation iodination. Probably the most commonly used technique is the chloramine T procedure, as it is relatively simple and inexpensive (for protocol see Slater, Ed., 2002).

Most experiments that involve iodinated proteins require a preparation that is free of unincorporated radioactive iodide. This is most commonly removed by either gel filtration or high performance liquid chromatography (HPLC).

Iodination of proteins is potentially one of the most hazardous techniques in molecular biology. The levels of ^{125}I employed are often in the region of 18.5 MBq (500 μCi). Rigid application of the principles of radiation protection is required, labeling should be carried out only by highly trained personnel with the permission of the radiation protection advisor, and a controlled facility is usually required (for example, if the level of ^{125}I used exceeds 10 MBq).

6 Detection

6.1 Ionization Monitors

An ionization monitor consists of a small gas chamber containing two electrodes, a voltage supply, and a scaler. Ionizing radiation enters through a thin end window, the gas is ionized and a pulse of current is recorded on the scaler, usually displayed as counts per second, counts per minute or Bq cm^{-2}. Gas ionization monitors are suitable for detecting ^{32}P, and they will pick up ^{14}C, ^{35}S and ^{33}P if a sensitive instrument with a very thin end window is used. They do not detect ^{3}H, because the β-particles cannot penetrate the end window. The instruments detect ^{125}I, but not particularly effectively, since electromagnetic radiation passes through the gas and results in relatively poor ionization.

The monitors must be regularly checked and officially calibrated annually. If you use ^{32}P, it is also worthwhile to do a simple calibration on your instrument for your own information. Place a known volume of ^{32}P in a plastic tube with the lid off and record the decay rate at various distances above the tube. Monitoring 0.1 MBq ^{32}P at 10 cm (equivalent to a dose rate of approximately 0.5 μSv min^{-1}) should give a reading in excess of 50 c.p.s. All personnel working with radioisotopes (except ^{3}H) should have constant access to a monitor while at the bench.

6.2 Scintillation Counters

These instruments work on the principle that certain substances (termed *scintillators* or *fluors*) emit light upon absorption of ionizing radiations. The scintillators can be solids (e.g. sodium iodide) or liquids (e.g. toluene). The light is detected by one or more photomultiplier tubes that give an electrical signal to a scaler. The number of electrical signals relates to the number of disintegrations in the sample, and the

strength of the signal relates to the energy of the absorbed radiation.

Scintillation probes are small handheld instruments useful for monitoring electromagnetic radiation (X or γ), say from ^{125}I. They either display c.p.s. values or, for dosimetry purposes, μSv h^{-1}. One of these instruments should be available whenever ^{125}I is used. As with ionization monitors, they should be calibrated officially once per year. You can calibrate them approximately yourself as an aid to monitoring (see Sect. 6.1).

Bench scintillation counters are designed for the analysis of large numbers of experimental samples. They either contain solid scintillators for detection of X or γ radiation or are designed for liquid scintillation counting. The latter instruments are found in most biochemical laboratories and are designed particularly for detecting β-emitters. The sample, usually in liquid form, is pipetted into a small container (or vial) to which a scintillation fluid is added.

There are many recipes for scintillation fluids (often referred to as cocktails). They are based on an organic solvent and one or more solutes termed *primary fluors* (when one solute is used) or *primary and secondary fluors* (when two solutes are used). The purpose of these fluors is to enhance the light output and shift the wavelength to the optimum for photomultiplier tubes. Most laboratories buy their cocktails ready prepared, and the manufacturer's catalogue should be carefully consulted. Essentially there are three forms of cocktail: a relatively straightforward formulation for counting organic samples, detergent-containing fluids for counting aqueous samples, and fluids that form gels for counting dispersed powders. The most commonly used ingredients are toluene or xylene as solvent, PPO (2,5-diphenyloxazole) or butyl-PBD (2-(4-t-butylphenyl)-5-(4-biphenyl)-l,3,4-oxadiazole) as primary solute, POPOP (l,4-bis(5-phenyloxazol-2-yl)benzene) as secondary solute and Triton-X100 as detergent.

An important concept in liquid scintillation counting is *quench*. This is anything that reduces counting efficiency, for example, colored compounds or chemicals such as chloroform that interfere with the scintillation process. Because a range of experimental samples may be subject to differing degrees of quench, it is necessary to calculate the counting efficiency of every sample individually. This can be done by re-counting samples following the addition of known amounts of radioactivity (an internal standard). However, this is tedious where there are a large number of samples, and contributes to the problem of waste disposal. Consequently, instruments have in-built means for automatically determining the counting efficiency. This works by counting a solid source of radioactivity within the machine that irradiates the sample vial. When quenching occurs, the energy spectrum of the radiation, as detected by the photomultipliers, appears to shift to lower-energy values. Analysis of this shift results in an assessment of counting efficiency within the sample vial. The instrument then corrects for the efficiency and prints out data as d.p.m. This system works well in most cases. However, it is essential to realize that it can be relied upon only when the sample is in solution in the vial, and is not appropriate for heterologous systems such as counting filter papers placed in scintillation fluid. This is because the filter paper will absorb some radiation, while the automatic quench correction mechanism will be recording only the properties of the solution. To accurately assess counting efficiency on filter

papers, the paper has to be removed after counting, a known aliquot of radioisotope applied, the filter re-dried, and counted again. The increase in counts divided by the known added radioactivity provides the counting efficiency.

The ability of scintillation counters to analyze the energy of radiations is of great value. Radioisotopes have characteristic energy spectra. If these are sufficiently different, a scintillation counter can detect radioisotopes separately, even when they are present in the same vial. Beta spectra are all similar in shape but different radioisotopes have differing maximum energies (see Table 2); thus ^{3}H, ^{14}C, and ^{32}P for example, can be distinguished by their energy spectra. This means that dual labeling experiments with these radionuclides is feasible.

The only way to monitor for ^{3}H is to perform wipe tests with damp tissues, and count in a liquid scintillation counter, but if other forms of contamination were present, they would be detected by the counter on the basis of spectral analysis. The fact that different isotopes have differing energies means that scintillation counters can be used to some extent to determine types of contamination (e.g. to determine whether the contamination is ^{3}H or ^{14}C).

Liquid scintillation counting sometimes presents two problems, *photoluminescence* and *chemiluminescence*, that result in light output from scintillation fluid that is not the result of radioactivity. That is, the c.p.m. will exceed the true d.p.m. It is caused by storage of scintillation fluid in bright sunlight, or by certain chemicals. Most modern counters are able to detect it and make a note to that effect on the printout. If in doubt, samples can be stored in the dark for a few hours, and then recounted.

6.3 Cerenkov Counting

High-energy β-particles travel through water faster than light; they cause polarization of molecules along their path, and these emit photons of light as they return to a ground state. The energy of radiation from ^{32}P is high enough to cause the Cerenkov effect. Consequently water can be used in place of scintillation fluid for this radioisotope. The counting efficiency is relatively low (about 30% compared with >90% in a scintillation cocktail) and the counter should be specifically calibrated for it, although an acceptable shortcut is to count the samples as if they were ^{3}H. The big advantages of Cerenkov counting are: aqueous samples can be counted and recovered for experimental use, and there is no accumulation of organic radioactive waste. It is also very inexpensive.

6.4 Autoradiography

Many experiments in molecular biology rely on this technique, in particular, analysis of nucleic acid samples separated on gels (southern and northern blotting) or detection of particular clones or plaques by hybridization screening. The basic principle underlying autoradiography is that light, a β-particle, X ray, or γ-ray can produce silver atoms in the crystals of silver halide that are present in photographic emulsions. This process is reversible if only a single atom of silver produced from one photon, forms in a crystal. However, silver atoms catalyze the conversion of silver halide to silver by the chemicals in the developer; this stabilizes the image.

Tab. 5 Use and sensitivity of autoradiography and fluorography.

Isotope	*Method*	*Example applications*	*Preflashed film*	*Inensifying screen*	*Temp. of exposure*	*Approximate detection limit after 24 h exposure [dpm/cm^{-2}]*
^{3}H	Direct	Whenever very high resolution is required, e.g. *in situ* hybridization	No	No	Room temp.	8×10^{6}
	Fluorography	Acrylamide gels	Yes	No	−70 °C	8×10^{3}
^{14}C, ^{35}S or ^{33}P	Direct	DNA sequencing	No	No	Room temp.	6×10^{3}
	Indirect	SDS-polyacrylamide gels	Yes	Yes	−70 °C	4×10^{2}
^{32}P	Direct	DNA sequencing	No	No	Room temp.	5×10^{2}
	Indirect	Southern analysis	Yes	Yes	−70 °C	5×10^{1}
^{125}I	Direct	Subcellular localization	No	No	Room temp.	2×10^{3}
	Indirect	Western blotting	Yes	Yes	−70 °C	1×10^{2}

If the radiation is of very low energy (e.g. from ^{3}H) it cannot penetrate very far and would, for example, be absorbed by the matrix of an agarose or polyacrylamide gel. Conversely, if radiation is very penetrating (e.g. from ^{32}P or ^{125}I) it passes through film without giving up much of its energy and is less efficiently detected than might be expected. To combat these difficulties there are techniques called *fluorography*, where samples such as gels are impregnated with fluors such as PPO (see Sect. 6.2), and *indirect autoradiography*, where intensifying screens partly absorb penetrating radiation and emit light. These adaptations increase sensitivity but reduce resolution. In both of these cases, exposure at low temperature is required to stabilize the latent image. In addition, a brief (<1ms) flash of light is required to preexpose the film and make it more responsive to low signals. Specific films are sold for direct or indirect autoradiography. A summary of some of the key features of autoradiography and fluorography (including use of intensifying screens) is provided in Table 5.

As discussed in Sect. 2, it is a requirement that if alternatives to radioisotopes are available, they should be used wherever possible. Nonradioactive labeling methods for DNA and proteins are improving all the time. Light-based detection techniques seem particularly successful in western blotting, for example. In the case of ^{32}P, a general rule at present is that if acceptable results are obtained within a 24-hour exposure to autoradiography, then a nonradioactive alternative should be sought. If longer exposures are required, particularly with intensifying screens, then it is likely that ^{32}P is still required for meeting the necessary sensitivity parameters.

6.5 Personal Dosimeters

These are either film badges or thermoluminescent detectors (TLDs). The latter contain a phosphor such as LiF that becomes and remains excited once exposed to radiation. Heat treatment results in light emission, the intensity of which relates to the dose received. Small TLDs can be worn on the fingers, under gloves, for hand dosimetry.

Personal dosimeters are not appropriate for workers using low-energy emitters such as ^{14}C, ^{35}S or ^{3}H but they are of value to users of ^{32}P or ^{125}I. Their issue should beon the advice of senior staff with appropriate training and responsibility for radiation protection, after dosimeter calculations and estimates of exposure levels to individuals.

Keywords

BAC
A bacterial artificial chromosome, a large-insert (~200 kb) cloning vector for genomic sequences.

Contig
A contiguous set of overlapping segments of DNA.

Finished sequence
Complete, contiguous sequence generated with an accuracy of 1 error per 10 000 bp.

Genome
The entire complement of nuclear DNA in an individual or the representative sequence composite from several individuals.

Nonsynonymous
Nucleotide changes in the coding region of a gene that change the amino acid sequence of the translated protein. Some amino acid changes are more deleterious to

the protein function than others. The nonsynonymous substitution rate is the number of nonsynonymous substitutions per nonsynonymous site K_A.

ORF
Open reading frame – a sequence that translates without internal stop codons into a protein sequence.

Orthologous
Sequence regions in different organisms that originated from the same sequence in the last common ancestor of the organisms.

Scaffold
A set of contigs with sequence gaps between them that are linked by mate-pair information or marker information that may or may not give an estimated gap size.

Synonymous
Nucleotide changes in the coding region of a gene that do not change the amino acid sequence of the translated protein. The synonymous substitution rate is the number of synonymous substitutions per synonymous site K_S.

Whole-genome Shotgun (WGS)
Sequence generated randomly from a genome. Usually sheared genomic DNA is subcloned into a library in plasmid vectors, the library is then sampled and clones sequenced from both ends of the inserts.

The Brown Norway rat was the third mammalian genome to be sequenced. The three-way comparison of the human, rat, and mouse sequences resolves details of mammalian evolution and allows divergence events to be placed on different branches of the evolutionary tree. The comparison of the human to invertebrate and rodent genomes highlights the consequences of evolution over 1000 million years and 75 million years, while the comparison of the two rodent genomes describes changes that occurred in the 12 to 24 million years since the common ancestor of the rat and mouse.

A number of insights came from these comparisons:

The rat genome is 2.75 gigabases (Gb), smaller than human (2.9 Gb), and slightly larger than mouse (2.6 Gb). The three genomes encode similar numbers of genes. The majority of the genes have persisted without deletion or duplication and with well-conserved intron–exon structures. The exceptions are members of gene families that have expanded through gene duplication. Genes found in rat, but not mouse included genes producing pheromones, or involved in immunity, chemosensation, detoxification, or proteolysis.

Human genes known to be associated with disease have orthologs in the rat, but their rates of synonymous substitutions are significantly different from other genes.

Three percent of the rat genome is in large segmental duplication, primarily located near the centromeres. Expansions of major gene families are due to these genomic duplications.

About 40% of the rat genome aligns orthologously to mouse and human; this eutherian core of the genome contains the vast majority of exons and known regulatory elements (which comprise 1–2% of the genome). Only a portion of this core (5–6%) appears to be under selective constraint in rodents and primates, while the remainder appears to be evolving neutrally. Outside the eutherian core, the majority of the 30% of the rat genome that aligns only with mouse is rodent-specific repeats. More than half of the nonaligning sequence is rat-specific repeats.

More genomic changes have occurred in the rodent lineages than in the primate. Large rearrangements include approximately 250 rearrangements between a murid ancestor and human (the majority between the eutherian ancestor and the murid ancestor, and approximately 50 each from the murid ancestor to the rat and mouse). There is a threefold higher base substitution rate in neutral DNA along the rodent lineage than along the human lineage, with the rate on the rat branch 5 to 10% higher than along the mouse branch. Microdeletions are more frequent than microinsertions in both the rat and mouse branches. Most interestingly, there is a strong correlation between local rates of microinsertions and microdeletions, nucleotide substitutions, and transposable element insertions in the rat and mouse lineages, although the events occurred independently since the divergence of the two branches.

1
The Rat and the Rat Genome

The rat, although revered as the first sign in the Chinese zodiac and bearer of the Hindu god Ganesh, is a known carrier of over 70 diseases. Rats are involved in the transmission of several infectious diseases to man, including cholera, bubonic plague, typhus, leptospirosis, cowpox, and hantavirus infections. A major agricultural pest, rats and other rodents consume approximately one-fifth of the annual food harvest.

The laboratory rat (*Rattus norvegicus*) has contributed to human health by testing new drugs, and improving the understanding of essential nutrients and the pathobiology of human disease. It was the first mammal domesticated for scientific research (1828). The rat has been the model of choice for physiologists and nutritionists, and there are over 234 inbred strains developed to study genetic diseases.

The rat genome-sequencing project produced a draft sequence that, unlike mouse and human, would not ultimately be finished to remove all sequence gaps and produce a high base accuracy. For this reason, the quality of the draft was important. Although gaps remained, the overall sequence quality supported detailed analyses.

The sequence was generated from two inbred females, (BN/SsNHsd/Mcwi) by a network of centers led by the Human Genome Sequencing Center, Baylor College of Medicine. An international team representing over 20 groups contributed to the analysis reported and summarized here.

2 The Assembly Strategy and Results

The rat genome project used a combined WGS (whole-genome shotgun) with BAC clone strategy (Fig. 1). The project benefited from the logistically simpler WGS sequence generation and the local sequence assembly to resolve duplications afforded by BAC clones. The Atlas assembly suite, designed to combine these data sets, provided a BAC fisher to present localized combined BAC + WGS data to the public prior to the availability of the complete assembly.

Over 44 million DNA sequence reads were generated (Table 1). After removal of low-quality reads and vector contaminants, 36 million reads were used in the assembly where 34 million reads were retained. This was a sevenfold sequence coverage, with 60% of the reads from the WGS. Coverage estimates range from 7.3x (when estimated from the entire ''trimmed'' length of the sequence data) to 6.9x (when estimated from the sequence with quality of Phred20 or higher).

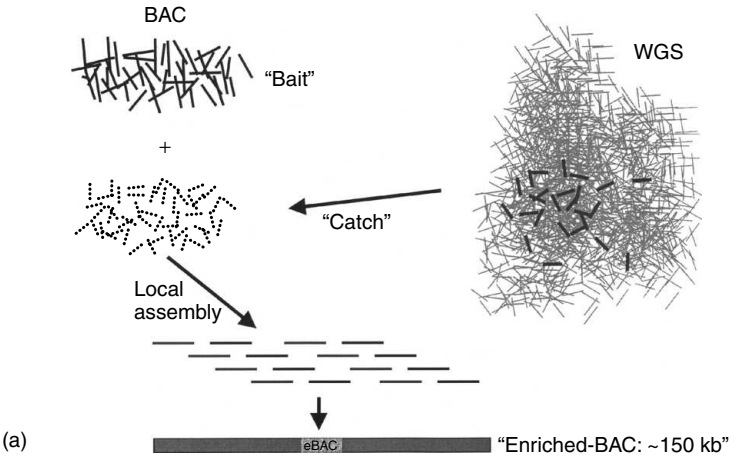

Fig. 1 The new ''combined'' sequence strategy and Atlas software. (a) Formation of ''eBACs.'' The strategy combined the advantages of both BAC and WGS sequence data. Modest sequence coverage (~1.8-fold) from a BAC is used as ''bait'' to ''catch'' WGS reads from the same region of the genome. These reads, and their mate pairs, are assembled using Phrap to form an enriched BAC or ''eBAC.'' This stringent local assembly retains 95% of the ''catch.'' (b) Creation of higher-order structures. Multiple eBACs are assembled into bactigs on the basis of sequence overlaps. The bactigs are joined into superbactigs by large clone mate-pair information (at least 2 links), extended into ultrabactigs using additional information (single links, FPC contigs, synteny, markers), and ultimately aligned to genome mapping data (RH and physical maps) to form the complete assembly. Used with permission from *Nature* **428**, 493–521 (2004).

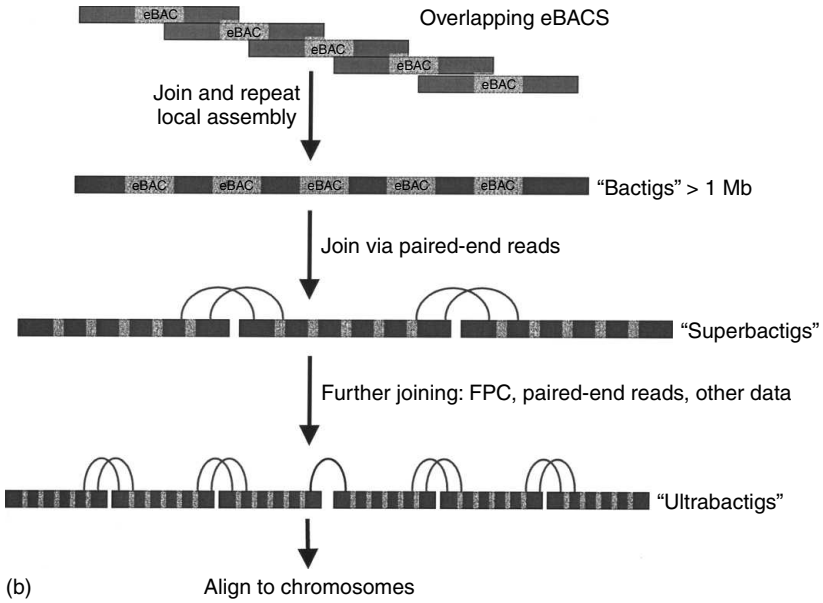

Fig. 1 (*Continued*)

Simultaneous to the sequencing, a ''fingerprint contig'' (FPC) map was developed, which was used in combination with the ongoing sequencing to identify BACs for sequence skimming. The parallel development of mapping and sequencing resources permitted the data-gathering phase of the project to be completed in less than two years.

The statistics of the rat draft assembly (v. 3.1) are given in Table 2. The current assembly (v. 3.4) splices in a number of finished BAC sequences to the v. 3.1 assembly. Much of the gene and protein feature analysis was developed using earlier assemblies (v. 2.0 and 2.1), while the genome description is based on v. 3.1.

The majority of the genome is in contigs larger than the expected mammalian gene (N50 = 38 kb). These contigs are linked into 783 larger scaffolds; those anchored to the radiation hybrid map had an N50 of 5.4 Mb, while the smaller scaffolds that could not be anchored had an N50 of 1.2 Mb.

The quality of the assembled sequence was assessed using sequence from finished BACs, the comparison showed that the bases within contigs were of high quality (1.32 mismatches per 10 kb), similar to the finished sequence. The majority of mismatches occurred at the ends of contigs in regions that average 750 bp and total <0.9% of the genome. Only six mismatches (insertions or deletions) were found within contigs when compared to 13 Mb of finished sequence or one per 2.2 Mb.

The assembly accuracy was judged in comparison to linkage and radiation hybrid maps. The majority of the genetic markers (13/3824) and sequence-tagged sites (96.9%) had consistent chromosome placement (Fig. 2). The maps are congruent with the assembly except for possible mismapped markers.

[a]Anchored sequences are those that can be placed on chromosomes because they contain known markers. The main scaffold for each superbactig is the largest set of contigs (in terms of total contig sequence), which can be ordered and oriented using mate-pair links and ordering of BACs. Scaffolds, which cannot be ordered and oriented with respect to the main scaffold, are termed *minor scaffolds*.
[b]Ambiguous bases (Ns) are counted in the gap sizes, and excluded in the base counts.
[c]Computed as bases plus gaps divided by estimated genome size. Sampled genome size is based on oligonucleotide frequency statistics of unassembled WGS reads. Assembled genome size is based on cumulative contig sequence following assembly.

3
Features of the Rat Genome

3.1
Genome Size

Genome assemblies are usually smaller than the actual genome size owing to underrepresentation of sequences due to cloning bias and sequencing and assembly difficulties. However, equating assembled genome size with the euchromatic, clonable portion of the genome (CpG) does not take into account the heterochromatic sequence included in the assembly. The rat genome size was estimated by two methods: scaling the assembled genome size by the fraction of features found in the assembly, and measuring the clonable or sampled genome size on the basis of the distribution of short oligomers in the WGS reads before assembly and in the assembly. Both estimates gave a relatively consistent measure of estimated genome size of 2.75 Gb. This conservative estimate was still considerably higher than the size estimated for the mouse draft genome sequence, which has different repeat content and appears to have underrepresented segmental duplications because of technical reasons.

3.2
Telomeres and Centromeres

The rat has both metacentric and telocentric chromosomes, unlike the wholly telocentric mouse chromosomes. As expected, the draft sequence does not contain complete telomere and centromere sequences. The approximate physical location of the centromeres relative to the genomic sequence is shown in Fig. 3. Several of the putative centromere positions coincide with segmental duplication blocks and classical satellite repeat clusters, consistent with enrichment of these sequence features in rat pericentromeric DNA. Human subtelomere regions are characterized by an abundance of segmentally duplicated DNA and an enrichment of internal (TTAGGG)n-like sequence islands.

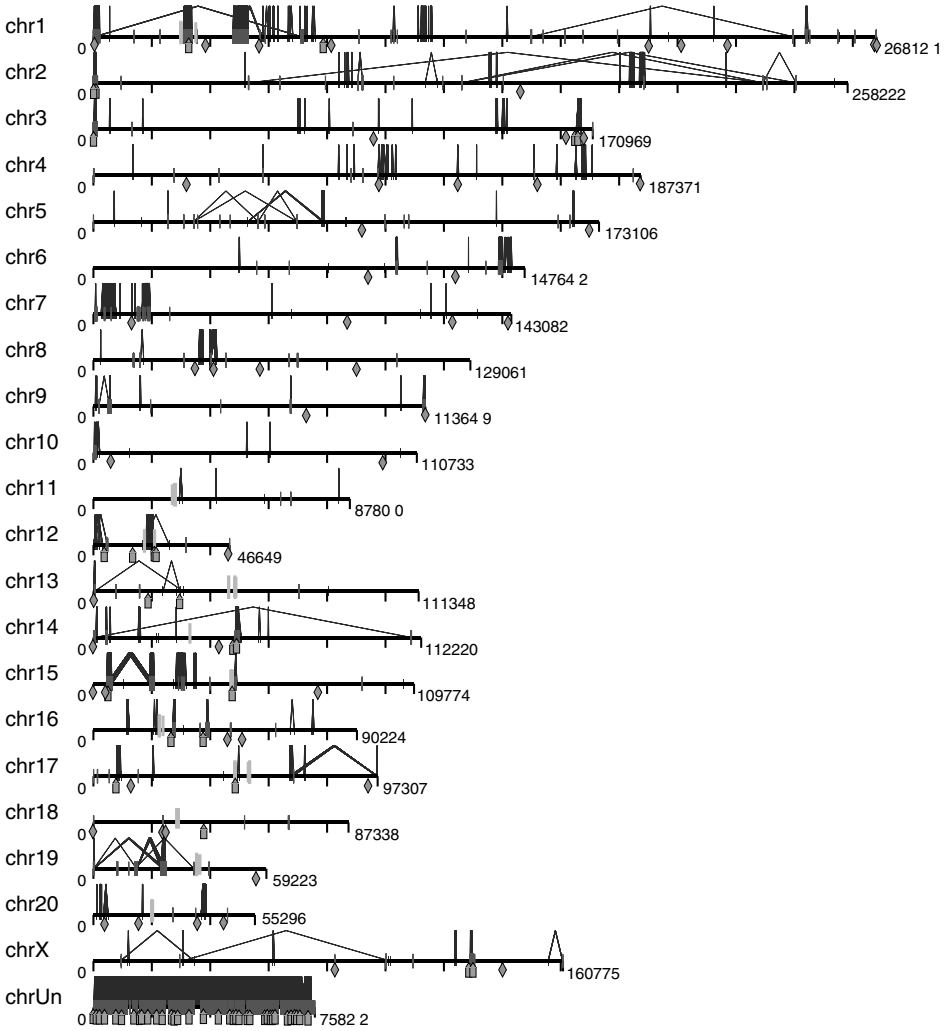

Fig. 3 Distribution of segmental duplications in the rat genome. Interchromosomal duplications (red) and intrachromosomal duplications (blue) are depicted for all duplications with ≥90% sequence identity and ≥20 kb length. The intrachromosomal duplications are drawn with connecting blue line segments; those with no apparent connectors are local duplications very closely spaced on the chromosome (below the resolution limit for the figure). P arms on the left and the q arms on the right. Chromosomes 2, 4–10, and X are telocentric; the assemblies begin with pericentric sequences of the q arms, and no centromeres are indicated. For the remaining chromosomes, the approximate centromere positions were estimated from the most proximal STS/gene marker to the p and q arm as determined by fluorescent *in situ* hybridization (FISH) (cyan vertical lines; no chromosome 3 data). The chrUn sequence is contigs not incorporated into any chromosomes. Green arrows indicate 1-Mb intervals with more than tenfold enrichment of classic rat satellite repeats within the assembly. Orange diamonds indicate 1-Mb intervals with more than tenfold enrichment of internal (TTAGGG)*n*-like sequences. For more details, see http://ratparalogy.cwru.edu. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. xlvi.)

Approximately one-third of the euchromatic rat subtelomeric regions contain similar features, suggesting that Rnor3.1 might extend very close to the chromosome ends.

3.3 Orthologous Chromosomal Segments and Large-scale Rearrangements

Multimegabase regions of chromosomes have been passed from the primate-rodent ancestor to human and murid rodent descendants with minimal rearrangements of gene order. These regions, bounded by the breaks that occurred during ancient large-scale chromosomal rearrangements are referred to as *orthologous chromosomal segments*. The sequence of these rearrangements was tentatively reconstructed using the human genome and other outgroup data (see Fig. 4). Inspection shows events that preceded and follow the rat–mouse divergence are interleaved. At 1-Mb resolution, multiple methods report virtually indistinguishable sets of orthologous chromosomes segments: 278 between human and rat, 280 between human and mouse, and 105 between rat and mouse. The larger numbers of breaks in orthologous segments between the human and the rodents is expected because of the greater evolutionary distance.

Understanding the number and timing of rearrangement events that have occurred in each of the three individual lineages (see tree in Fig. 5a) since the common primate-rodent ancestor required a more detailed analysis. The X chromosome is presented here as an example; its history is easier to trace completely since rearrangements between the X and the autosomes are rare. There are 16 human–mouse–rat orthologous segments of at least 300 kb in size (Fig. 6a). The most parsimonious scenario requires 15 inversions in the descent from the primate-rodent ancestor. Outgroup data from cat, cow, and dog resolve the timing of these rearrangements more precisely. Most of these events occurred in the rodent lineage: five (or four) before the divergence of rat and mouse, five in the rat lineage and five in the mouse lineage. At most one rearrangement occurred in the human lineage since divergence from the common ancestor with rodents. The analysis of the whole genome showed similar results. The assignment of the considerable rearrangement activity to the rodent branch following primate-rodent divergence is consistent with previous, lower resolution studies.

3.4 Segmental Duplications

Segmental duplications are defined here as genomic regions of at least 5 kb in length that are repeated with >90% identity remaining between the copies. The rat has approximately 2.9% of its bases in these duplicated regions, whereas the human has 5 to 6%, and the mouse has 1.0 to 2.0%. These duplicated structures are particularly challenging to assemble, so some of the mouse–rat difference is attributable to the BAC-based approach used in the rat assembly compared to the WGS-mouse approach. Most of these regions have less than 99.5% identity and are, therefore, not simply overlapping sequences that were not joined by the assembly program. Nearly 44% of these blocks of segmental duplications are mapped to the ''unplaced'' chromosome in Rnor3.1 indicating the difficulty of anchoring these elements to the genome.

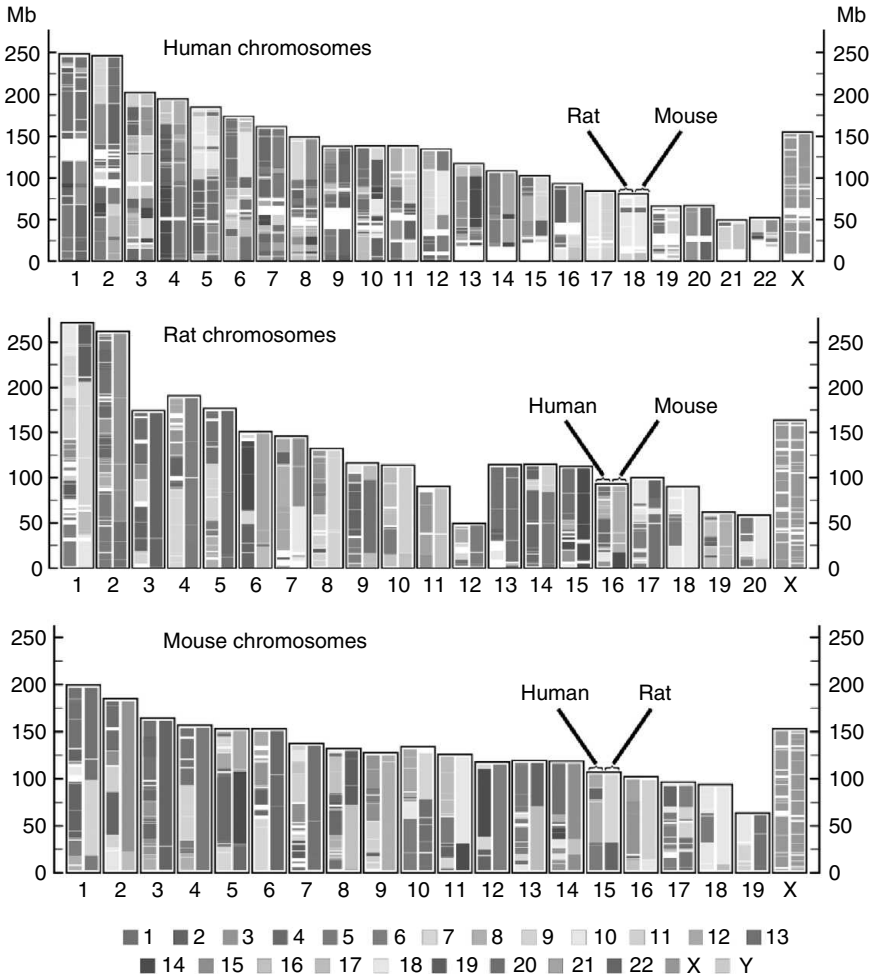

Fig. 4 Map of conserved synteny between the human, mouse, and rat genomes: For each species, each chromosome (*x*-axis) is a two column boxed pane (p-arm at the bottom) colored according to conserved synteny to chromosomes of the other two species. The same chromosome color code is used for all species (indicated below). For example, the first 30 Mb of mouse chromosome 15 is shown to be similar to part of human chromosome 5 (by the red in left column) and part of rat chromosome 2 (by the olive in right column). An interactive version is accessible (http://www.genboree.org). Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. xlvii.)

Intrachromosomal duplications are three times more common than interchromosomal duplications and are significantly enriched near the telomeric and centromeric regions (Fig. 3). The pericentromeric accumulation of segmental duplications in the rat seems to be a general property of mammalian chromosome architecture.

There is considerable clustering of segmental duplications. For many of the largest clusters, the underlying sequence

Fig. 5 Substitutions and microindels (1–10 bp) in the evolution of the human, mouse, and rat genomes: (a) The lengths of the labeled branches in the tree (top panel) are proportional to the number of substitutions per site inferred from all sites with aligned bases in all three genomes. (b) The table shows the midpoint and variation in these branch length estimates when estimated from different sequence alignment programs and different neutral sites, including sites from ancestral repeats, fourfold degenerate sites in codons, and rodent-specific sites (''in neutral sites only'' row). Other rows give midpoints and variation for microindels on each branch of the tree. Used with permission from *Nature* **428**, 493–521 (2004).

alignments show a wide range of sequence identity, suggesting that duplication events have occurred continuously over millions of years. In contrast, an analysis of all duplicated regions showed a bimodal distribution consistent with bursts of segmental duplication (particularly intrachromosomal duplication) that occurred approximately 5 and 8 Myr ago.

The segmental duplications of the rat genome were of considerable interest because they represent an important mechanism for the generation of new genes. Sixty-three (of 4532 total) NCBI reference sequence genes were completely or partially located within duplicated regions. As discussed in the following, many of these genes present in multiple copies, belong to recently duplicated gene families, and contribute to distinctive elements of rat biology.

3.5 Gains and Losses of DNA

In addition to large rearrangements and segmental duplications, genome architecture is strongly influenced by insertion and deletion events that add and remove DNA over evolutionary time. To characterize the origins and losses of sequence elements in the human, mouse, and rat genomes, the nucleotide bases were categorized using alignment data and annotations of the insertions of repetitive elements (Fig. 7).

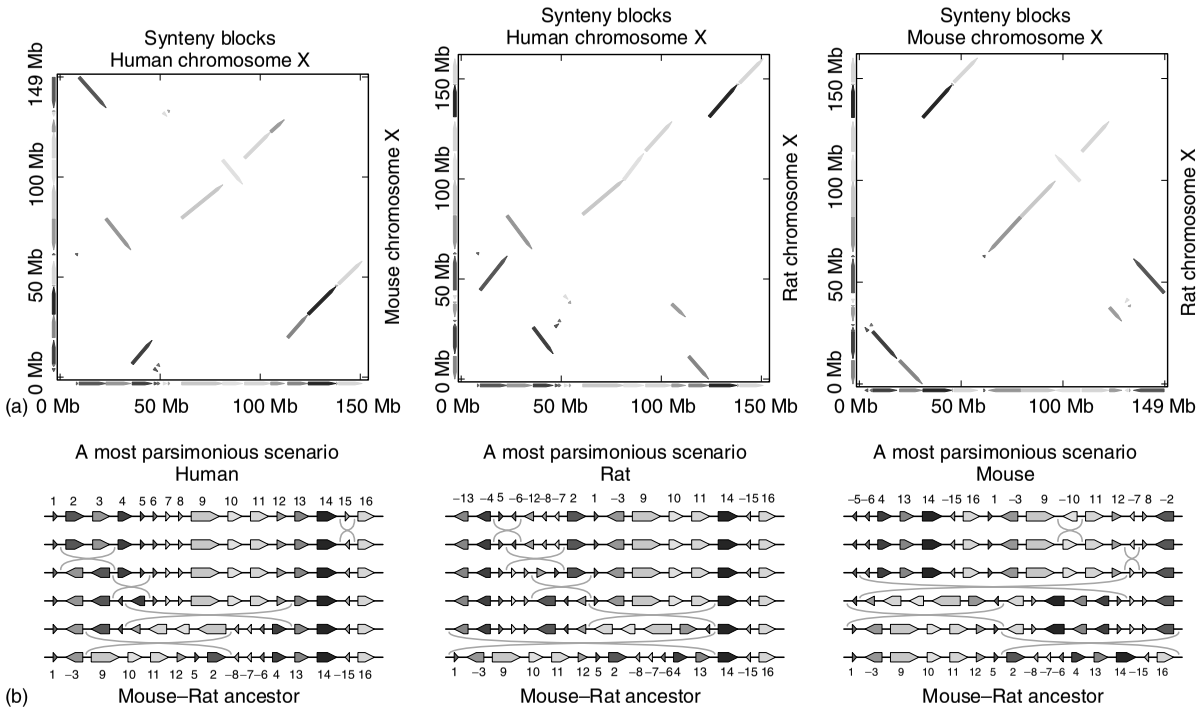

Fig. 6 X chromosome in each pair of species: (a) GRIMM–Synteny computes 16 three-way orthologous segments (≥300 kb) on the X chromosome of human, mouse, and rat, shown for each pair of species, using consistent colors. (b) The arrangement (order and orientation) of the 16 blocks implies that at least 15 rearrangement events occurred during X chromosome evolution of these species. The program MGR determined that evolutionary scenarios with 15 events are achievable and all have the same median ancestor (located at the last common mouse–rat ancestor). Shown is a possible (not unique) most parsimonious inversion scenario from each species to that ancestor. Note the last common ancestor of human, mouse, and rat should be on the evolutionary path between this median ancestor and human. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. lv.)

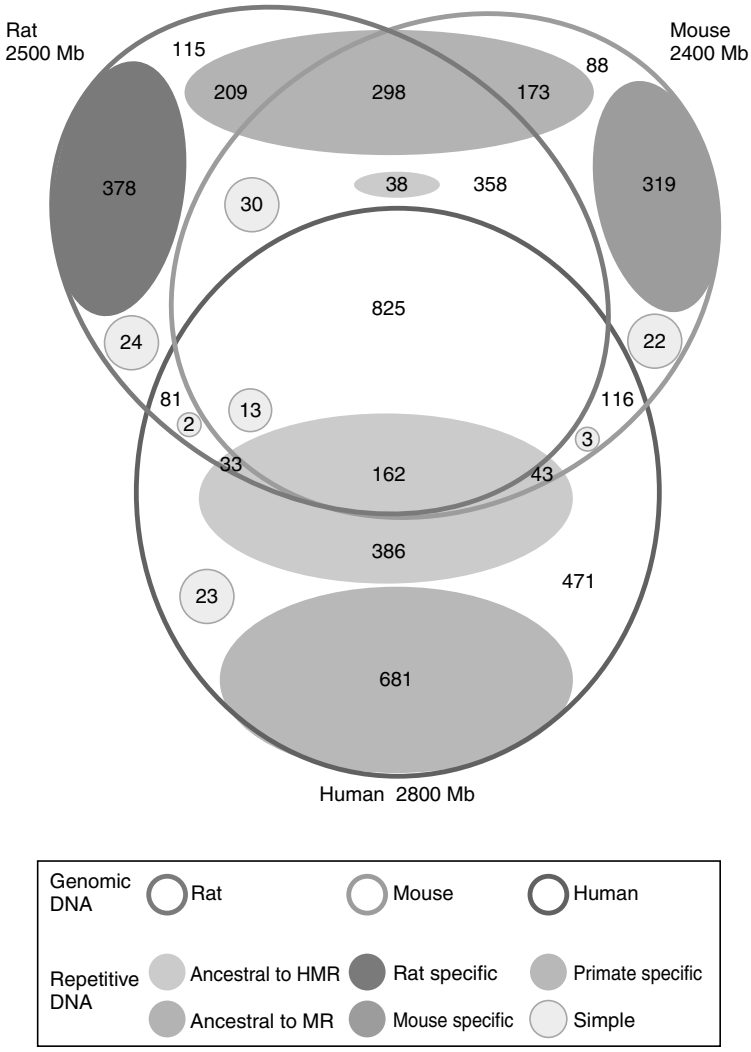

Fig. 7 Aligning portions and origins of sequences in rat, mouse, and human genomes. Each outlined ellipse is a genome, and the overlapping areas indicate the amount of sequence that aligns in all three species (rat, mouse, and human) or in only two species. Nonoverlapping regions represent sequences that do not align. Types of repeats classified by ancestry: those that predate the human–rodent divergence (gray), those that arose on the rodent lineage before the rat–mouse divergence (lavender), species-specific (orange for rat, green for mouse, blue for human), and simple (yellow), placed to illustrate the approximate amount of each type in each alignment category. Uncolored areas are nonrepetitive DNA – the bulk is assumed to be ancestral to the human–rodent divergence. Numbers of nucleotides (in Mb) are given for each sector (type of sequence and alignment category). Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. xlviii.)

The estimates of the amount of repeats represent lower bounds because some repeats, especially the older ones, are not recognized even though the rodent repeat database was greatly expanded by analyzing the rat and mouse genomes.

About a billion nucleotides (39% of the euchromatic rat genome) align in all three species, constituting an ''ancestral core,'' which is retained in these genomes. The ancestral core contains 94 to 95% of the known coding exons and regulatory regions. The levels of three-way conservation of ''mammalian ancestral repeats'' (transposon relics retained in all three species) confirm estimates that 5 to 6% of the human genome is accumulating substitutions more slowly than the neutral rate in the three lineages, and hence may be under purifying selection. In this constrained fraction, noncoding regions outnumber coding regions regardless of the constrain, an observation that supports comparative analyses on limited subsets of the genome. The preponderance of noncoding elements in the most constrained fraction of the genome underscores the likelihood that they play critical roles in mammalian biology.

About 700 Mb (28%) of the rat euchromatic genome aligns only with the mouse. At least 40% of this is rodent-specific repeats that are inserted on the branch from the primate-rodent ancestor to the murid ancestor. Some of the remainder is ancestral mammalian repeats or single copy DNA deleted in the human lineage but retained in rodents (Fig. 7). Although this 700 Mb of rodent-specific DNA is primarily neutral, it may also contain some functional elements lost in the human lineage in addition to sequences representing gains of rodent-specific functions, including some coding exons.

3.6 Substitution Rates

The alignment data allow relatively precise estimates of the rates of neutral substitutions and microindel events (<=10 bp). As in previous studies comparing human and mouse, both synonymous fourfold degenerate (''4D'') sites in protein-coding regions and sites in mammalian ancestral repeats were used in this analysis. In addition, the primarily neutral rodent-specific sites that did not align to human discussed earlier were used.

Estimates for the neutral substitution level between the two rodents range from 0.15 to 0.20 substitutions per site, while estimates for the entire tree of human, mouse, and rat range from 0.52 to 0.65 substitutions per site (Fig. 5). This difference was predictable because of the evolutionary closeness of the two rodents. Less predictable was the finding that for all classes of neutral sites analyzed, the branch connecting the rat to the common rodent ancestor is 5 to 10% longer than the mouse branch. Thus, for as yet unknown reasons, the rat lineage has accumulated substantially more point substitutions than the mouse lineage since their last common ancestor.

Four-way alignments with sequence from orthologous ancestral repeats in the three genomes and the repeat consensus sequences (to approximate the progenitor repeat sequence) were used to distinguish substitutions on the branches from the primate-rodent ancestor to either the human or rodent ancestor. This revealed a three-to-one speed-up in rodent substitution rates relative to human, larger than estimated in the mouse analysis but consistent with more recent studies, which also use multiple sequence alignments.

Estimates for rates of microdeletion events are, for all branches, approximately twofold higher than rates of microinsertion (Fig. 5b), suggesting a fundamental difference in the mechanisms that generate these mutations. Furthermore, there are substantial lineage specific rate differences. The rat lineage has accumulated microdeletions more rapidly than the mouse, while the opposite holds true for microinsertions. As with substitutions, both microinsertions and microdeletion rates are substantially slower in the human lineage. The size distributions of microindels (1–10 bp) were heavily weighted toward the smallest indels and similar for insertions, deletions, and both the mouse and rat branches.

3.7 *G + C* Content and CpG Islands

The G + C content of the rat varies significantly across the genome (Fig. 8a) in a distribution that more closely resembles that of mouse than human. The variation of G + C content is coupled with differences in the distribution of CpG islands – short regions that are associated with the 5′ ends of genes and gene regulation and that escape the depletion of CpG dinucleotides owing to deamination of methylated cytosine. The 2.6-Gb rat genome assembly contains 15 975 CpG islands in nonrepetitive sequences of the genome. This is similar to the 15 500 CpG islands reported in the 2.5-Gb mouse genome, but far fewer than the 27 000 reported in the human genome. The distribution of CpG islands by chromosome is shown in Fig. 8b.

The changes in CpG island content predate the rat-mouse split and are consistent with the accelerated loss of CpG dinucleotides in rodents compared with humans. It remains possible, however, that the greater number of human regions with extremely high G + C content are due to distributational changes occurring in the primate, rather than the rodent lineage.

3.8 Shift in Substitution Spectra between Mouse and Rat

The nonrepetitive fraction of the rat genome is enriched for G + C content relative to the mouse genome by ~0.35% over 1.3 billion nucleotides. This is a subtle but substantial difference that may be explained in part by differences in the spectra of mutation events that have accumulated in the mouse and rat lineages. The small minorities of substitutions where events can be assigned to either the mouse or the rat lineage by virtue of a nucleotide match in the alignment column between human and only one rodent were studied. Of the ~117 million alignment columns meeting this criteria, ~60 million involve a change in the rat lineage versus ~57 million in the mouse, reflecting the increase in the rates of point substitution in the rat lineage (Fig. 5b). Fifty percent of these events in rat involve a substitution from an A/T to a G/C compared to only 47% of all mouse changes. The complementary change, G/C to A/T, is more common in the mouse lineage (38% vs. 35% in rat). There is not a similar substantial difference between changes that do not alter G + C content. In addition, this bias is not confined to particular transition or transversion events, nor can it be explained simply as a result of divergent substitution rates of CpG dinucleotides. Thus, this shift appears to be a general

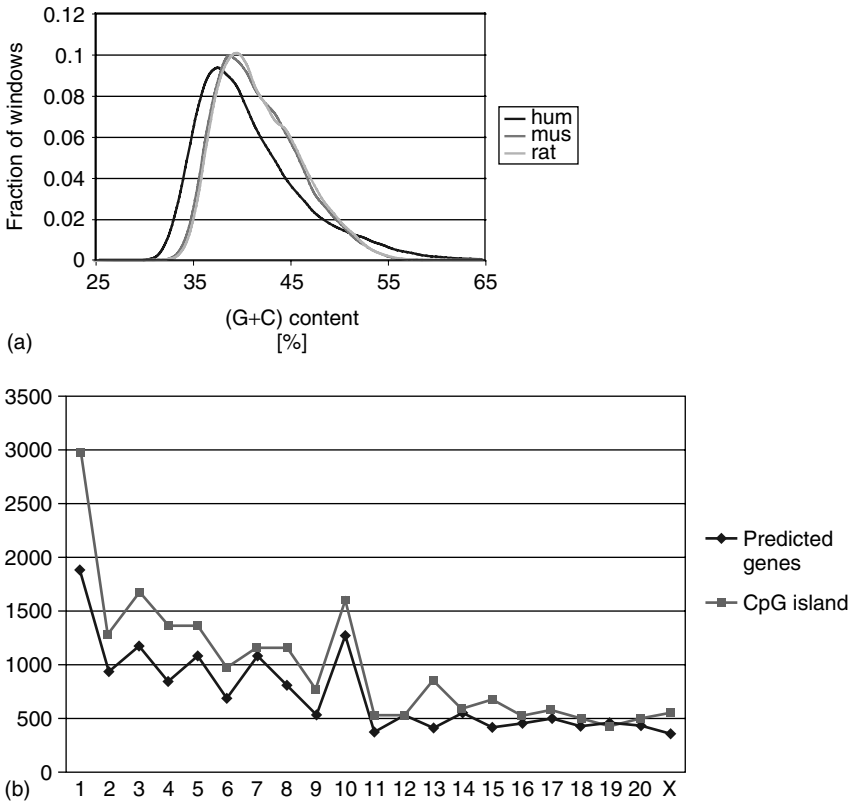

Fig. 8 Base composition distribution analysis. (a) The fraction of 20 kb nonoverlapping windows with a given G + C content is shown for human, mouse, and rat. (b) The number of Ensembl predicted genes per chromosome and the number of CpG islands per chromosome. The density of CpG islands averages 5.9 islands per Mb across chromosomes and 5.7 islands per Mb across the genome. Chromosome 1 has more CpG islands than other chromosomes, yet neither the island density nor ratio to predicted genes exceeds the normal distribution. The number of CpG islands per chromosome and the number of predicted genes are correlated ($R^2 = 0.96$). Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. xlix.)

change that results in an increase in G + C content in the rat genome. Biochemical changes in the repair or replication enzymes might be responsible, and the observation that recombination rates are slightly higher in rat than in mouse may suggest a role for G + C biased mismatch repair. However, population genetic factors, such as selection, cannot be ruled out.

3.9 Evolutionary Hotspots

Comparison of the two rodent genomes, using human as outgroup, reveals regions that are conserved yet under different levels of constraint in mouse and rat. These regions may have distinct functional roles and contribute to species-specific differences. In 5055 regions >=100 bp,

with at least a tenfold difference in the estimated number of substitutions per site on the mouse and rat branches and <0.25 substitutions per site on the human branch (to avoid fast-evolving regions), analysis found them enriched twofold in transcribed regions. Thirty-nine percent of mouse hot spots were found in 18% of the

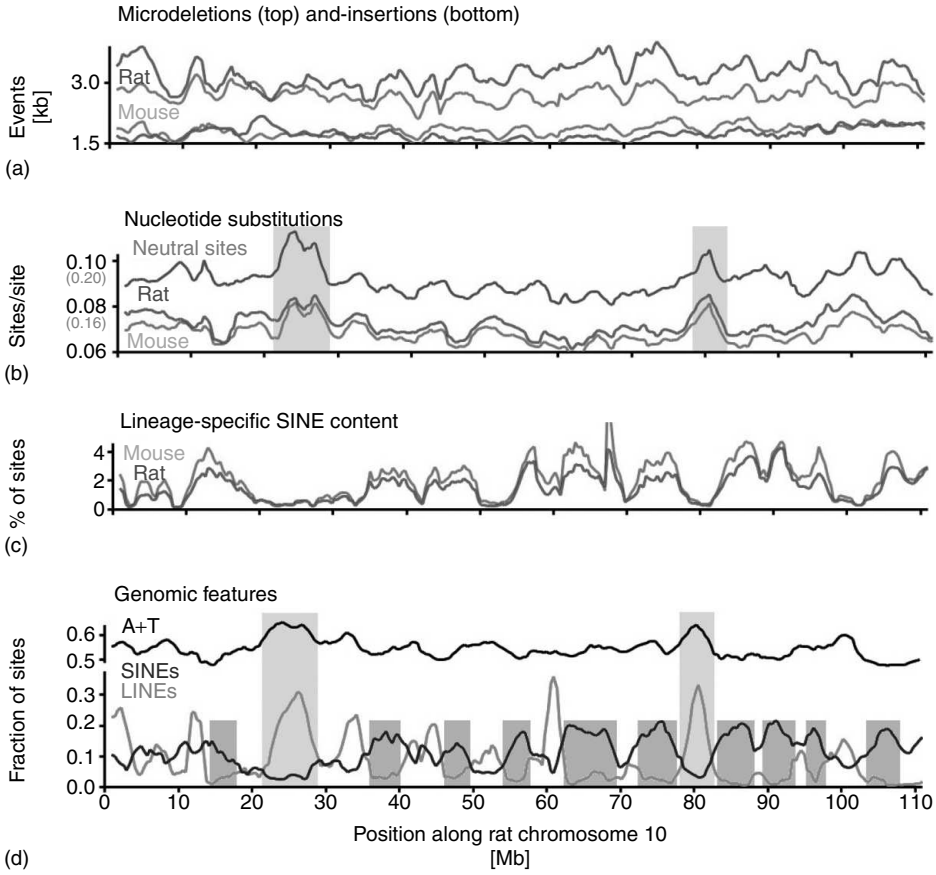

Fig. 9 Variability of several evolutionary and genomic features along rat chromosome 10. (a) Rates of microdeletion and microinsertion events (less than 11 bp) in the mouse and rat lineages since their last common ancestor, revealing regional correlations. (b) Rates of point substitution in the mouse and rat lineages. Red and green lines represent rates of substitution within each lineage estimated from sites common to human, mouse, and rat. Blue represents the neutral distance separating the rodents, as estimated from rodent-specific sites. Note the regional correlation among all three plots, despite being estimated in different lineages (mouse and rat) and from different sites (mammalian vs rodent-specific). (c) Density of SINEs inserted independently into the rat or mouse genomes after their last common ancestor. (d) A + T content of the rat, and density in the rat genome of LINEs and SINEs that originated since the last common ancestor of human, mouse, and rat. Pink boxes highlight regions of the chromosome in which substitution rates, AT content, and LINE density are correlated. Blue boxes highlight regions in which SINE density is high but LINE density is low. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. l.)

mouse genome covered by RefSeq genes; and 17% of rat hotspots were found in 8% of the rat genome covered by RefSeq genes. Similar numbers were also observed with coding exons and EST regions. Half of all hotspots in the mouse genome lie totally in noncoding regions.

3.10 Covariation of Evolutionary and Genomic Features

A high-resolution analysis of the genomic and evolutionary landscape of rat chromosome 10 uncovered strong correlations between certain microevolutionary features. Strongly correlated, in particular, are the local rates of microdeletion ($R2 = 0.71$; Fig. 9a), microinsertion ($R2 = 0.56$; Fig. 9a), and point substitution ($R2 = 0.86$; Fig. 9b) between the two independent lineages of mouse and rat. In addition, microinsertion rates are correlated with microdeletion rates ($R2 = 0.55$; Fig. 9a). These strong correlations are also observed in an independent genome-wide analysis, both on the original data and after factoring out the effects of G + C content. Perhaps surprisingly, substantially less correlation is seen between microindel and point substitution rates (compare Figs. 9a and b).

The local point substitution rate in sites common to human, mouse, and rat strongly correlates with that in rodent-specific sites ($R2 = 0.57$; Fig. 9b, blue line versus red/green). These two classes of sites, while interdigitated at the level of tens to thousands of bases, constitute sites that are otherwise evolutionarily independent. This result confirms that local rate variation is not solely determined by stochastic effects and extends, at high resolution, the previously documented regional correlation in rate between 4D sites and ancestral repeat sites.

4 Evolution of Genes

A substantial motivation for sequencing the rat genome was to study protein-coding genes. Besides being the first step in accurately defining the rat proteome, this fundamental data set yields insights into differences between the rat and other mammalian species with a complete genome sequence. Estimation of the rat gene content is possible because of relatively mature gene-prediction programs and rodent-transcript data. Mouse and human genome sequences also allow characterization of mutational events in proteins such as amino acid repeats and codon insertions and deletions. The quality of the rat sequence also allows us to distinguish between the functional genes and pseudogenes.

An estimated 90% of rat genes possess strict orthologs in both mouse and human genomes. Studies also identified genes arising from recent duplication events occurring only in rat, and not in mouse or human. These genes contribute characteristic features to rat-specific biology, including aspects of reproduction, immunity, and toxin metabolism. In contrast, almost all human ''disease genes'' have rat orthologs. This underscores the importance of the rat as a model organism in experimental science.

4.1 Construction of Gene Set and Determination of Orthology

The Ensembl gene-prediction pipeline has predicted 20 973 genes with 28 516 transcripts, and 205 623 exons in rat. These genes contain an average of 9.7 exons, with a median exon number of 6.0. At least 20% of the genes are alternatively spliced, with an average of 1.3 transcripts predicted per

gene. Of the 17% single exon transcripts, 1355 contain frameshifts relative to the predicted protein and 1176 are likely processed pseudogenes. The majority of transcripts are supported by rodent (61%) or vertebrate (72%) transcript evidence, and have at least one untranslated region predicted (60%). The coding densities ranged from 1.2 to 2.2% and the coding fraction of RefSeq genes covered by these predictions ranged from 82 to 98%. The number of coding exons per gene and average exon length were similar in the three species. Differences were observed in intron length, with an average of 5338 bp in human, 4212 bp in mouse, and 5002 bp in rat.

4.2 Properties of Orthologous Genes

Orthology relationships were conservatively predicted and 12 440 rat genes showed clear, unambiguous 1 : 1 correspondence with a gene in the mouse genome. Accounting for potential errors 86 to 94% of the rat genes have 1 : 1 mouse orthologs. The remaining genes were associated with lineage-specific gene family expansions or contractions. Surprisingly, a similar proportion (89–90%) of rat genes possessed a single ortholog in the human genome, perhaps because of less resolution in the draft genomes. The majority of nucleotide changes within protein-coding regions that reflected synonymous or nonsynonymous substitutions yielded K_A/K_S ratios of less than 0.25 indicating purifying selection. Values of 1 suggest neutral evolution, and values greater than 1 indicate positive selection. Examination of ortholog pairs in orthologous genomic segments (Table 3) showed a slight increase in median K_S values, indicating that the rat lineage has more neutral substitutions in gene coding regions than the mouse lineage.

Rat genes shared with mouse, but with no counterparts in human are expected to reflect either a rapidly evolving gene set, or genes that may have arisen from noncoding DNA, or been converted to pseudogenes in the human lineage. Thirty-one ENSEMBL rat genes were collected that have no nonrodent homolog in current databases. These are twofold overrepresented among genes in paralogous gene clusters, and threefold overrepresented among genes whose proteins are likely to be secreted. This is consistent with observations that clusters of paralogous genes, and secreted proteins, evolve relatively rapidly.

Tab. 3 1 : 1 orthologous genes in human, mouse, and rat genomes[b].

	Human/Mouse	*Human/Rat*	*Mouse/Rat*

The paucity of rodent-specific genes indicates that *de novo* invention of complete genes in rodents is rare. This is not unexpected, since the majority of eukaryotic protein-coding genes are modular structures containing coding and noncoding exons, splicing signals, and regulatory sequences; and the chances of independent evolution and successful assembly of these elements into a functional gene are small, given the relatively short evolutionary time available since the mouse–rat split. However, individual rodent-specific exons may arise more frequently, particularly if the exon is alternatively spliced. Of the 2302 potential novel rodent-specific exons, with transcript support, none matched human transcripts but approximately half (1116) appear to be present in alternative splice forms found in rodents. These exons are speculated to contain the few successful lineage-specific survivors of the constant process of gene evolution, by birth and death of individual exons.

4.3 Indels and Repeats in Protein-coding Sequences

In contrast to small indels occurring in the bulk of the genome, indels within protein-coding regions are likely lethal, or deleterious, and rapidly removed from the population by purifying selection. Indel rates within rat coding sequences were 50-fold lower than in bulk genomic DNA. The whole genome excess of deletions compared to insertions (Fig. 5b) was also evident in coding sequences. Deletions are ~16% more likely than insertions to be removed from coding sequences by selection.

Owing to the triplet nature of the genetic code, indels of multiples of 3 nucleotides in length (3n indels) are less likely to be deleterious. Direct comparison of 3n indel rates between bulk DNA (0.77 indel/kb for mouse, 0.83 indel/kb for rat) and coding sequence (0.087 indel/kb for mouse and 0.084 indel/kb for rat) showed that 3n indels were ninefold underrepresented in coding sequences. At least 44% of indels were duplicative insertion or deletion of a tandemly duplicated sequence, collectively termed *sequence slippage*. Sequence slippage contributed approximately equally to observed insertions and deletions, the overall excess of deletions could be attributed specifically to an excess of nonslippage deletion over nonslippage insertion in both mouse and rat lineages. Of slippage indels, 13% were trinucleotide repeats known to be particularly prone to sequence slippage and encode homopolymeric amino acid tracts.

Other characteristics of amino acid repeat variations were searched to gain better understanding of dynamic changes in length of homopolymeric amino acid tracts on gene evolution and disease susceptibility. Most species-specific amino acid repeats (80–90%) were found in indel regions and regions encoding species-specific repeats were more likely to contain tandem trinucleotide repeats than those encoding conserved repeats. This was consistent with involvement of slippage in the generation of novel repeats in proteins and extended previous observations for glutamine repeats in a more limited human–mouse dataset.

The percentage of proteins containing amino acid repeats was 13.7% in rat, 14.9% in mouse, and 17.6% in human. The most frequently occurring tandem amino acid repeats were glutamic acid, proline, alanine, leucine, serine, glycine, glutamine, and lysine. Tandem trinucleotide repeats were significantly more abundant in human than in rodent coding sequences, in

striking contrast to the frequencies observed in bulk genomic sequences (29 trinucleotide repeats/Mb in rat, 32 repeats/Mb in mouse and 13 repeats/Mb in human, Sect. 5.5). The conservation of human repeats was higher in mouse (52%) than in rat (46.5%), suggesting a higher rate of repeat loss in the rat lineage than in the mouse lineage.

Functional consequences of these in-frame changes in rat, mouse, and human were investigated through clustering of proteins based on annotation of function and cellular localization, and mapping indels onto protein structural and sequence features. The rate that indels accumulated in secreted (3.9×10^{-4} indel/aa) and nuclear (4.0×10^{-4}) proteins is approximately twice that of cytoplasmic (2.4×10^{-4}) and mitochondrial (1.4×10^{-4}) proteins. Likewise, ligand-binding proteins acquire indels (3.1×10^{-4}) at a higher rate than enzymes (2.1×10^{-4}). These trends exactly mirror those observed for amino acid substitution rates, suggesting tight coupling of selective constraints between indels and substitutions. Transcription regulators showed the highest rate of indels (4.3×10^{-4}), a finding that may relate to the overrepresentation of homopolymorphic amino acid tracts in these proteins.

Known protein domains exhibited 3.3-fold fewer indels than expected by chance, again paralleling nucleotide substitution rate differences between domains and nondomain sequences. Transmembrane regions were refractory to accumulating indels, exhibiting a sixfold reduction compared to that expected by chance. Low-complexity regions were 3.1-fold enriched, reflecting their relatively unstructured nature and enrichment for indel prone trinucleotide repeats. Mapping of indels onto groups of known structures revealed indels are 21% more likely to be tolerated in loop regions than the structural core of the protein.

An interesting observation was indel frequency and amino acid repeat occurrence both correlated positively with G + C coding sequence content of the local sequence environment. This may in part be explained by the correlation of polymerase slippage-prone trinucleotide repeat sequences and G + C content. There is also a positive correlation between CpG dinucleotide frequency and coding sequence insertions, but not deletions. This effect diminishes rapidly with increasing distance from the site of the insertion.

4.4 Transcription-associated Substitution and Asymmetry

A significant strand asymmetry for neutral substitutions in transcribed regions has been reported. Within an intron the higher rate of A → G substitutions over that of T → C substitutions, together with a smaller excess of G → A over C → T substitutions, leads to an excess of G + T over C + A on the coding strand. The asymmetries are hypothesized to be a by-product of transcription-coupled repair in germline cells. Examining the 3-way alignments of rat, mouse, and human verified that the strand asymmetries for neutral substitutions exist in introns across the rat genome (Table 4). These asymmetries are also seen if the study is limited to ancestral repeat sites, excludes ancestral repeat sites, excludes CpG dinucleotides, is limited to positions flanked by sites that are identical in the aligned sequences (in the case of observations 2 and 3 in Table 4), or considers introns of RefSeq genes for human or mouse. Thus, it appears that strand asymmetry of substitution events

Tab. 4 Strand asymmetry of substitutions in introns of rat genes.

1	Base frequencies on coding strand	Rat genome	
	$(G + T)/(C + A)$	1.060	
2	Ratio of purine transitions to pyrimidine transitions	Rat–Mouse	Rat–Human
	rate($A \leftrightarrow G$)/rate($C \leftrightarrow T$)	1.036	1.036
3	Rate of transitions	Rat	Mouse
	rate($A \rightarrow G$)/rate($T \rightarrow C$)	1.058	1.091
	rate($G \rightarrow A$)/rate($C \rightarrow T$)	1.017	1.00*

Data in (1) were computed from the rat genome, those in (2) were computed from pairwise alignments, and data in (3) were computed from 3-way alignments. All values except * were highly significant (p-values $<10^{-4}$).

within transcribed regions of the genome is a robust genome-wide phenomenon.

4.5 Conservation of Intronic Splice Signals

The dynamics of evolution of consensus splice signals in mammalian genes was examined using 6352 human–mouse–rat orthologous introns from 976 genes. Intron class is extremely well conserved: no conversion between U2 and U12 introns, nor switching within U12 introns between the major AT–AC and GT–AG subtypes was observed, although U12 switching has been documented at larger evolutionary distances. In contrast, conversions between canonical GT–AG and noncanonical GC–AG subtypes of U2 introns are not uncommon. Only ~70% of GC–AG introns are conserved between human and mouse/rat, and only 90% are conserved between mouse and rat. Using human as outgroup, we detected 9 GT to GC conversions after divergence of mouse and rat (from 6282 introns likely to be GT–AG prior to human and rodents split), and 2 GC to GT conversions (from 34 GC–AG introns likely to predate human and rodent split). Given the higher rate of conversion from GT to GC than the reverse, these results give some indication of the degree to which mutation from T to C is tolerated in donor sites. This substitution appears to be better tolerated in introns with very strong donor sites, since in these introns the proportion of GC donor sites is ~11%, which is much higher than the 0.7% overall frequency of GC donor sites in U2 introns. Very few other noncanonical configurations in U2 introns are conserved, suggesting that most correspond to transient, evolutionarily unstable states, pseudogenes, or misannotations.

4.6 Gene Duplications

Duplication of genomic segments represents a frequent and robust mechanism for generating new genes. Since there were no compelling data showing rat-specific genes arising directly from noncoding sequences, gene duplications were examined to measure their potential contribution to rat-specific biology. A previous study showed such gene clusters in mouse without counterparts in human are subject to rapid, adaptive evolution. Using methods that directly identified paralogous clusters found 784 rat paralog clusters containing 3089 genes. This was lower than in mouse (910 clusters per 3784 genes), but the difference probably reflects the

larger number of gene predictions from the mouse assembly. Using methods that analyzed genomic segmental duplications, it appears that the timing of expansion of these individual families, is reflected in local gene duplication and retention within clusters. Neutral substitution rate varies among orthologs by approximately twofold (Fig. 10). Rates of change among ancestral gene duplications (those that predate the mouse/rat split) were relatively constant. Mouse-specific and rat-specific duplications occurred at similar rates, except for those with $K_S < 0.04$ that are reduced in mouse-specific duplications (Fig. 10), though this may be accounted for by different assembly methods.

The rat paralog pairs that probably arose after the rat/mouse split (12–24 Myr ago) have a K_S value of ≥ 0.2 (Table 3). Six hundred and forty nine $K_S < 0.2$ gene duplication events were found in rat, a lower number than found in mouse (755). For both rodents, this represents a likelihood of a gene duplicating between 1.3×10^{-3} and 2.6×10^{-3} every Myr. This is consistent with a previous estimate for Drosophila genes, and an order of magnitude lower than an estimate for *Caenorhabditis elegans* genes.

Immunoglobulin, T-cell receptor α-chain, and α_{2u} globulin genes appear to be duplicating at the fastest rates in the rat genome (Table 5). Since divergence with mouse, these rat clusters have increased gene content severalfold. This recapitulates previous observations that rapidly evolving and duplicating genes are overrepresented in olfaction and odorant-detection, antigen

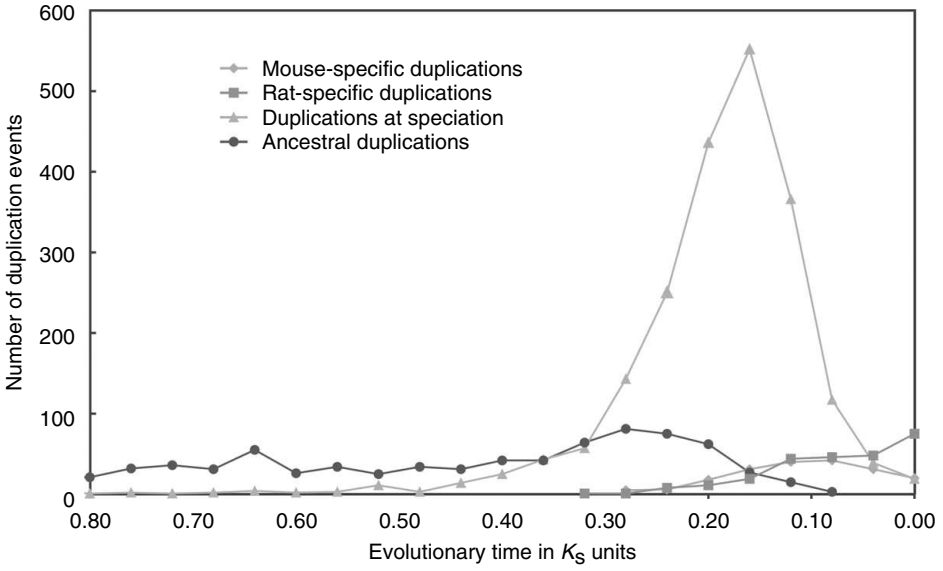

Fig. 10 Variation in the frequency of gene duplications during the evolutionary histories of the rat and mouse. The sequence of gene duplication events was inferred from phylogenetic trees determined from pairwise estimates of genetic divergence under neutral selection (K_S). The median K_S value for mouse:rat 1 : 1 orthologs is 0.19; this value corresponds to the divergence time of the mouse and rat lineages. Used with permission from *Nature* **428**, 493–521 (2004).

Tab. 5 Recent gene duplications ($K_S < 0.2$) in the rat lineage. Duplications involving retroviral genes, fragmented genes with internal repeats, and likely pseudogene clusters were removed from this list. Only gene clusters exhibiting at least 3 duplications are shown.

recognition, and reproduction. An examination of duplicated genomic segments showed this enrichment for most of the same genes and also elements involved in foreign compound detoxification (cytochrome P450 and carboxylesterase genes). Together these are exciting findings because each of these categories can easily be associated with a familiar feature of rat-specific biology, and further investigation could explain some differences between rats and their evolutionary neighbors.

4.7 Conservation of Gene-regulatory Regions

As the third mammal to be fully sequenced, the rat can add significantly to the utility of nucleotide alignments for identifying conserved noncoding sequences. This power increases roughly as a function of total amount of neutral substitution represented in the alignment, and rat adds about 15% to the human-mouse comparison (Fig. 5). Many conserved mammalian noncoding sequences are expected to have regulatory function, and can be predicted using further analyses based upon these alignments.

Typical genome-wide human–mouse–rat alignments show strong conservation for a coding exon, as well as for several noncoding regions (Fig. 11). For example, the intronic region, in Fig. 11 contains 504 bp that are highly conserved in human, mouse, and rat. The last 100 bp of this alignment block are identical in all three species. Peaks in regulatory potential score are correlated with conservation score, and in the highly conserved intronic segment, they are higher for the three-way regulatory potential score than for the two-way scores using human and just one rodent. These data are illustrative, but form the foundation of ongoing efforts to identify genome sequences involved in gene regulation.

Requiring conservation among mammalian genomes greatly increases specificity of predictions of transcription factor binding sites. Transcription factor databases such as TRANSFAC contain known transcription factor binding sites and some knowledge of their distribution, but simply searching a sequence with these motifs provides little discriminatory power. Using a set of 164 weight matrices for 109 transcription factors extracted from TRANSFAC finds 186 792 933 matches in the April 2003 reference human genome sequence, but this was reduced to only 4 188 229 by demanding conservation in the human–mouse–rat three-way alignments. This is a 44-fold increase in specificity.

4.8 Pseudogenes and Gene Loss

Pseudogenes found in rat were classified according to whether they arose from retrotransposition, in which case they integrated into the genome randomly, or whether they arose from tandem duplication and neutral sequence substitution. Using human–rat synteny, 80% of pseudogenes exhibited no significant similarity to the corresponding human orthologous region, and therefore were considered to be retrotransposed, processed pseudogenes. The total pseudogene count and processed pseudogene proportion are consistent with those found for human. Pseudogenes are normally not subjected to selective constraint and therefore accumulate sequence modifications neutrally. Indeed, nearly all of our identified pseudogenes ($97 \pm 3\%$) evolved under neutrality according to a

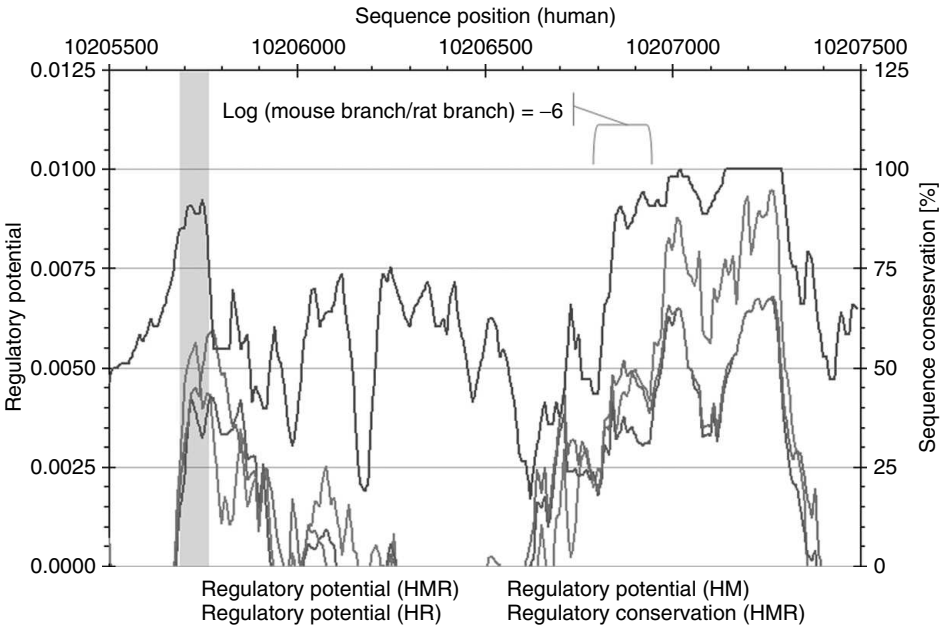

Fig. 11 Close-up of PEX14 (peroxisomal membrane protein) locus on human chromosome 1 (with homologous mouse chromosome 4 and rat chromosome 5). Conservation score computed on 3-way human–mouse–rat alignments presents a clear coding exon peak (gray bar) and very high values in a 504 bp noncoding, intronic segment (right; last 100 bp of alignment are identical in all three organisms). The latter segment showed a striking difference between the inferred mouse and rat branch lengths: the gray bracket corresponds to a phylogenetic tree where the logarithm of mouse to rat branch length ratio is −6. Regulatory potential (RP) scores that discriminate between conserved regulatory elements and neutrally evolving DNA are calculated from 3-way (human–mouse–rat) and 2-way (human-rodent) alignments. Here the 3-way regulatory potential scores are enhanced over the 2-way scores. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. li.)

K_A/K_S test, and therefore, are consistent with being pseudogenic.

As with the human genome, the largest group of rat pseudogenes (totaling 2188) consists of ribosomal protein genes. Other large rat pseudogene families arose from olfactory receptors (552, see Sect. 6.1), glyceraldehyde 3-phosphate dehydrogenase (251), protein kinases (177), and RNA binding RNP-1 proteins (174). Pseudogenes homologous to a meiotic spindle-associated protein spindlin are particularly numerous in rat (at least 53 copies), compared to mouse (approximately 3 copies). This suggests that spindlin pseudogenes may have distributed rapidly by a recently active transposable element.

4.9 *In Situ* Loss of Rat Genes

As an organism evolves, its need for certain genes may be reduced, or lost, owing to changes in its ecological niche. Loss of selective constraints leads to accumulation of nonsense and/or frameshift mutations without retrotransposition or duplication. These nonprocessed pseudogenes are

Tab. 6 Candidate rat pseudogenes, orthologous to mouse and human functional genes.

[b]Mouse genes were used as templates for predicting rat pseudogenes.

interesting since they link environmental changes to genomic mutation events. However, predicted pseudogenes with disrupted reading frames might also be indicative of errors in genome sequence or assembly. By constraining the search to orthologous genomic regions, we identified 14 rat putative nonprocessed pseudogenes (Table 6) with apparently functional, single human, and mouse orthologs.

4.10 Noncoding RNA Genes

The abundance and distribution of noncoding RNAs was investigated in rat. Cytoplasmic tRNA gene identification in rodents is complicated by tRNA derived ID SINE elements (B2 and ID). TRNAscan–SE predicted 175 943 tRNAs (genes and pseudogenes); however, the majority (175 285) were SINEs identified by RepeatMasker. This is far greater than found in mouse (24 402/25 078) or human (25/636). Of the remaining 666 predictions, 163 were annotated as tRNA pseudogenes and 4 were annotated as undetermined by tRNAscan–SE. An additional 68 predictions were removed because their best database match in either human, mouse, or rat tRNA databases matched tRNAs with either a different amino acid or anticodon (violating the wobble rules that specify the distinct anticodons expected). The total of 431 tRNAs (including a single selenocysteine tRNA) identified in the rat genome is comparable to that for mouse (435) and human (492). These three species share a core set of approximately 300 tRNAs using a cutoff of $\geq$95% sequence identity and $\geq$95% sequence length.

A total of 454 noncodingRNAs (other than tRNAs) were identified by sequence comparison to known noncoding RNAs. These include 113 micro (mi) RNAs, 5 ribosomal RNAs, 287 small nucleolar (sno) RNAs, and small nuclear (sn) RNAs; 49 various other ncRNAs such as signal recognition particle (SRP) RNA, 7SK RNA, telomerase RNA, Rnase P RNA, brain-specific repetitive (Bsr) RNA, noncoding transcript abundantly expressed in brain (Ntab) RNA, small cytoplasmic (sc) RNA, and 626 pseudogenes. Complete 18S and 28S rRNA genes and more rRNAs were not identified presumably owing to assembly issues.

5 Evolution of Transposable Elements

Most interspersed repeats are immobilized copies of transposable elements that have accrued substitutions in proportion to their time spent fixed in the genome (for introduction see references in Nature paper). About 40% of the rat genome draft is identified as interspersed repetitive DNA derived from transposable elements, similar to mouse (Table 7) and lower than for the human (almost 50%). The latter difference is mainly because of the lower substitution rate in the human lineage, which allows us to recognize much older (Mesozoic) sequences as interspersed repeats. Almost all repeats are derived from retroposons, elements that procreate via reverse transcription of their transcripts. As in mouse, there is no evidence for activity of DNA transposons since the rat–mouse split. Many aspects of the rat and the mouse genomes' repeat structure are shared; here we focus on the differences.

5.1 LINE-1 Activity in the Rat Lineage

The long interspersed nucleotide element (LINE-1 or L1) is an autonomous

Data for Rnor3.1 and October 2003 mouse (MM4), excluding Y chromosome, using the December 17 2003 version of RepeatMasker. To highlight the differences between rat and mouse repeat content, column 5 and 6 show the fraction of the genomes comprised of lineage specific repeats. The LINE-1 numbers include all HAL1 copies, while all BC1 scRNA and >10% diverged tRNA–Ala matches, far more common than other small RNA pseudogenes and closely related to ID, have been counted as ID matches.

retroelement, with an internal RNA polymerase II promoter and two open reading frames (ORFs). ORF1 is an RNA binding protein with chaperone-like activity suggesting a role in mediating nucleic acid strand transfer steps during L1 reverse transcription. ORF2 encodes a protein with both reverse transcriptase and DNA endonuclease activity. LINEs are usually 5′ truncated so that only a small subset extends to include the promoter region and can function as a source for more copies.

Many classes of LINE-like elements exist, but only L1 has been active in rodents. Over half a million copies, in variable stages of decay, comprise 22% of the rat genome. Although over 10% of the human genome is L1 copies introduced before the rodent–primate split, only 2% of the rat genome could be recognized as such because of the fast substitution rate in the rodent lineage. Thus, probably well over one quarter of all rat DNA is derived directly from the L1 gene.

Following the mouse/rat split, L1 activity appears to have increased in rat. The 6 rat-specific L1 subfamilies, represented by 150 000 copies, cover 12% of the rat genome. Mouse-specific L1 copies accumulated over the same period cover only 10% of the genome (Table 7). This greater accumulation of L1 copies could explain some of the size difference of the rat and mouse genome.

In addition to the traditional L1 elements, there are 7500 copies (10 Mb) of a nonautonomous element that is derived from L1 by deletion of most of its ORF2. On the basis of their low divergence, the presently identified HAL1-like (HAL1 for Half-a-LINE) elements operated only a few million years ago in the mouse lineage (MusHAL1) and still propagate in the rat genome (RNHAL1). RNHAL1 only contains an ORF1, while MusHAL1 encoded an endonuclease as well, though no reverse transcriptase. The repeated origin and high copy number of HAL1s suggests that the ORF1 product, which binds strongly to its mRNA, may render this transcript a superior target for L1 mediated reverse transcription. In this way, HAL1 resembles the nonautonomous, endogenous retrovirus-derived MaLR elements (in the following), which, for over 100 million years, retained only the retroviral gag ORF that encodes an RNA binding protein. A potential advantage of HAL1 over L1 is its shorter length, which, considering the usual 5′ truncation of copies, increases the chance that a copy includes the internal promoter elements and can become a source gene.

5.2 Different Activity of SINEs in the Rat and Mouse Lineage

The most successful usurpers of the L1 retrotransposition machinery are SINEs. These are small RNA-derived sequences with an internal RNA polymerase III promoter. The human Alu SINE was shown to be transposed by L1. L1 lacks sequence specificity and rodent and primate SINE sequences are unrelated to L1. Though any transcript can be retroposed, as evidenced by the numerous mammalian processed pseudogenes, L1-dependent SINEs probably have features that make them especially efficient targets of the L1 reverse transcriptase.

While before the radiation of most mammalian orders L1 was at least as active as L2, the L2 dependent MIR was the only known (and very abundant) SINE of that time. All of the currently active SINEs in different mammalian orders appear to have arisen after the demise of L2 (and consequently MIR), as if an opportunity (or necessity) arose for the creation and expansion of other SINEs.

Four different SINEs are distinguished in rat and mouse. The B1 element and the primate Alu originated from a 7SLRNA gene, probably just before the rodent–primate split and after the speciation from most other eutherians, where Alu/B1 elements are not known. The other SINEs (B4, B2, ID) are rodent-specific and have tRNA-like internal promoter regions.

The fortunes of these SINEs during mouse and rat evolution have been different (Fig. 12). B4 probably became extinct before the mouse–rat speciation, while B2 has remained productive in both lineages, scattering >100 000 copies in each genome after this time. Interestingly, the fate of the B1 and ID SINEs has been opposite in rat and mouse. While B1 is still active in mouse, having left over 200 000 mouse-specific copies in its trail, the youngest of the 40 000 rat-specific B1 copies are 6 to 7% diverged from their source, indicating a relatively early extinction in the rat lineage.

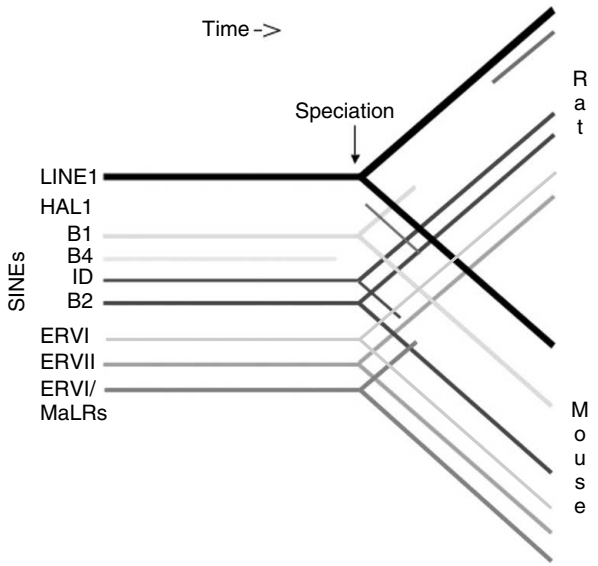

Fig. 12 Historical view of rodent repeated sequences. Relationships of the major families of interspersed repeats (Table 7) are shown for the rat and mouse genomes, indicating losses and gains of repeat families after speciation. The lines indicate activity as a function of time. Note that HAL1-like elements appear to have arisen both in the mouse and rat lineage. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. lii.)

On the other hand, after the mouse–rat split only a few hundred ID copies may have inserted in mouse, while this heretofore minor SINE (~60 000 copies predate the speciation) picked up activity in rat to produce 160 000 ID copies.

5.3 Colocalization of SINEs in Rat and Mouse

Although the fates of SINE families differ, the number of SINEs inserted after speciation in each lineage is remarkably similar, ~300 000 copies. As MIR was replaced by L1 driven SINEs, it appears that the demise of B1 in rat allowed the expansion of IDs. Moreover, these independently inserted and unrelated SINEs (ID and B1 only share a mechanism of retroposition) accumulated at orthologous sites: the density of rat-specific SINEs in 14 243 ~100 kb windows in the rat genome is highly correlated ($R^2 = 0.83$) with the density of mouse-specific SINEs in orthologous regions in mouse (Fig. 5). These data corroborate and refine the observation of a strong correlation between the location of primate and rodent-specific SINEs in 1-Mb windows. At 100 kb, no correlation is seen for interspersed repeats other than SINEs.

Insertions of SINEs at the same location have been reported, and the correlation could reflect the existence of conserved hotspots for SINE insertions. However, primate data does not support this. Likewise, gene conversions do not significantly contribute to the observed correlation.

Figure 9(c) displays the lineage-specific SINE densities on rat chromosome 10 and in the mouse orthologous blocks, showing a stronger correlation than any other feature. The cause of the unusual distribution patterns of SINEs, accumulating in gene-rich regions where other interspersed repeats are scarce, apparently is a conserved feature independent of the primary sequence of the SINE and effective over smaller than isochore-sized regions.

In the human genome, the most recent (unfixed) Alus are distributed similar to L1, whereas older copies gradually take on the opposite distribution of SINEs. However, this temporal shift in SINE distribution pattern is not observed in mouse or rat.

Some regions of high LINE content coincide with regions that exhibit both higher AT content and an elevated rate of point substitution (Fig. 9, pink rectangles). In a genome-wide analysis, LINE content correlates strongly with substitution rates, and about 80% of this correlation is explained by higher rates in AT-rich regions. SINE density shows the opposite correlation both on chromosome 10 (Fig. 9) and genome-wide.

These phenomena, in conjunction with an overall trend in substitution rates toward AT-richness, suggest a model by which quickly evolving regions accumulate a higher-than-average AT content, which attracts LINE elements. While distinct cause–effect relationships such as this remain largely speculative, these results reinforce the idea that local genomic context strongly shapes local genomic features and rates of evolution.

5.4 Endogenous Retroviruses and Derivatives

Retrovirus-like elements are the other major contributors to interspersed repeats in the rodent genome. These have several 100-bp long terminal repeats (LTRs) with transcriptional regulatory sequences that flank an internal sequence that, in autonomous elements, encodes all proteins necessary for retrotransposition. All mammalian LTR elements are endogenous retroviruses (ERVs; classes I, II, or III) or their nonautonomous derivatives.

The most productive retrovirus in mammals has been the class III element ERV-L, primarily through its ancient nonautonomous derivatives called ''MaLRs'' with 350 000 copies occupying ~5% of the rat genome (Table 7). Human ERV-L and MaLR copies are >6% diverged from their reconstructed source genes and must have died out around the time of our speciation from new world monkeys. In mouse, several thousand almost identical MaLR and ERV-L copies suggest sustained activity. In contrast, rat ERV-L activity was silenced a few million years ago given that the least diverged MaLR and ERV-L copies differ by >4% from each other. Other class III ERVs were active earlier in rodent evolution, before the mouse–rat speciation. Class I and class II elements still thrive in rat, where 2 of 4 class I and 4 of 9 class II autonomous ERVs appear to be active.

5.5 Simple Repeats

Interspersed simple sequence repeats (SSRs), regions of tandemly repeated (1–6 bp) units that probably arise from slippage during DNA replication and can expand and compress by unequal crossing over. Remarkable differences were noted between the human and mouse genomes' SSR content with threefold to fivefold more base pairs contained in near (>90%) perfect SSRs in mouse. SSRs are

both more frequent and on average longer in mouse. Polypurine (or polypyrimidine) repeats are especially (10-fold) overrepresented in the mouse genome. As discussed in Sect. 4.3, this contrasts sharply with the greater frequency of triplet repeats coding for amino acids in human relative to the rodents.

Rat and mouse SSR content are more similar, with genome coverage of ~1.4% (for >90% perfect elements compared to 0.45% in human) and are of similar average length. For example, the most common mammalian SSR, the (CA)n repeat, averages 42 bp long in mouse and 44 bp in rat. Some potentially significant differences are that polypurine SSRs are of similar average length but 1.2-fold more common in mouse, while the rare SSRs containing CG dimers are 1.5-fold more frequently observed in rat.

5.6 Prevalent, Medium-length Duplications in Rodents

In addition to the transpositionally derived and simple repeats, the rat and mouse genomes contain a substantial amount of medium-length unclassified duplications (typically 100–5000 bp). These are readily seen in self-comparisons and in intrarodent comparisons after masking the known repeats, but they are much less prevalent in comparisons with the human genome. A substantial fraction of the rodent genomes consists of currently unexplained repeats, which may include (1) novel families of low-copy rodent interspersed repeats; (2) extensions of known but not fully characterized rodent repeats; and (3) duplications generated by a mechanism different from transposition.

6 Rat-specific Biology

The rat genome sequence and predicted gene set reveals genetic differences between rats and mice that might specify their differences in physiology and behavior. In particular, recently duplicated genes are enriched in elements involved in chemosensation and functional aspects of reproduction (Table 5). The differences in the gene complements of rat and mouse are illustrated by in-depth analyses of olfactory receptors (ORs), pheromones, cytochromes P450, proteases, and protease inhibitors.

6.1 Chemosensation

The ability to emit and sense specific smells is a key feature of survival for most animals in the wild. Rat and mouse pheromones, vomeronasal receptors, and ORs genes were duplicated frequently during the time since the common ancestor of rats and mice (Table 5). The rapid evolution of these genes is attributed to conspecific competition, in particular sexual selection.

The rat genome has 1866 ORs in 113 locations: 69 multigene clusters, and 49 single genes. Extrapolating for the 9.8% of the genome not in the assembly, there are ~2070 OR genes and pseudogenes. The rat therefore has ~37% more OR genes and pseudogenes than the ~1510 ORs of the mouse, assuming similar representation of recently duplicated sequences in the two genome assemblies used. Of the 1774 OR sequences that are not interrupted by assembly gaps, 1216 (69%) encode intact proteins, while the remaining 547 (31%) sequences are likely pseudogenes with in-frame stop codons, frameshifts, and/or interspersed repeat

elements. Fewer mouse OR homologs are pseudogenes (~20%), but the larger family size in rat still leaves it with substantially more intact ORs than the mouse (~1430 vs ~1210). Striking rat-specific expansions of two ancestral clusters account for much of the difference in OR family size and pseudogene content between rat and mouse, although many other clusters exhibit more subtle changes. Significant differences between human and mouse in OR families have also been reported, but the functional implications of OR repertoire size on the ability of different species to detect and discriminate odorants are not yet known.

6.2
α_{2u} Globulin Pheromones

The α_{2u} globulin genes are odorant-binding proteins that also contribute to essential survival functions in animals. α_{2u} globulin homologs are likely to be highly heterogeneous among murid species. Distinct homologs and genomic arrangement differences have been observed among mouse strains. The evolution of α_{2u} globulin genes on rat chromosome 5 has remodeled this genomic region (Fig. 13). The orthologous human genomic region contains a single homolog, suggesting that the common ancestor of rodents and human possessed one gene. The genome of C57BL/6J mice contains 4 homologous genes, and 7 pseudogenes, while the rat genome contains 10α_{2u} globulin genes and 12 pseudogenes in a single region.

Phylogenetic trees constructed using amino acid, and noncoding DNA, sequences show that, surprisingly, the rat α_{2u} globulin gene clusters appear to have arisen recently via a rapid burst of gene duplication since the rat/mouse split (Table 5). This is consistent with the Rfp37-like zinc finger-like pseudogene having accompanied virtually all of the rat-specific α_{2u} globulin gene duplications (Fig. 13). The sequences of these genes are

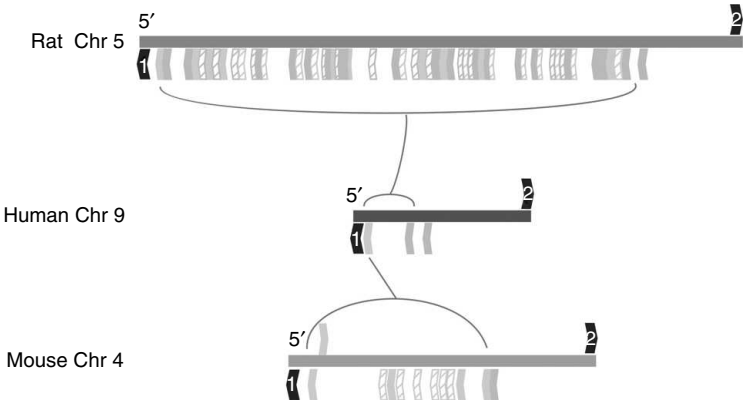

Fig. 13 Adaptive remodeling of genomes and genes. Orthologous regions of rat, human and mouse genomesencoding pheromone-carrier proteins of the lipocalin family (α_{2u} globulins in rat and major urinary proteins in mouse) shown in brown. Zfp37-like zinc finger genes are shown in blue. Filled arrows represent likely genes, whereas striped arrows represent likely pseudogenes. Gene expansions are bracketed. Arrow head orientation represents transcriptional direction. Flanking genes 1 and 2 are TSCOT and CTR1 respectively. (See color plate p. xliv.)

also evolving rapidly with median K_A/K_S values of 0.77 and 1.06, for rat and mouse genes respectively. Amino acid sites that appear to have been subject to adaptive evolution are situated both within the ligand-binding cavity, and on the solvent-exposed periphery of the α_{2u} globulin structure. This demonstrates how genome analysis can reveal the imprint of adaptive evolution from megabase to single base levels.

The rapid evolution of these genes, and the remodeling of their genomic regions, can be attributed to the known roles of rat α_{2u} globulins and mouse homologs in conspecific competition and sexual selection. These proteins are pheromones and pheromone carriers that are present in large quantities in rodent urine, and act as scent markers indicating dominance and subspecies identity.

6.3 Detoxification

Cytochrome P450 is a well-recognized participant in metabolic detoxification and rapid evolution is observed within this family. These enzymes are particularly relevant to clinical and pharmacological studies in humans as they metabolize many toxic and endogenous compounds. Rodents are important model organisms for understanding human drug metabolism, so it is important to identify 1:1 orthologs and species-specific expansions and losses. Compared to human genes, there are clear expansions of several rodent P450 subfamilies, but there are also significant differences between rat and mouse subfamilies (Fig. 14a). The fastest evolving subfamily seems to be CYP2J containing a single gene in human, but at least 4 in rat and 8 in mouse (Fig. 14b,c). CYP2J enzymes catalyze the NADPH-dependent oxidation of arachidonic acid to various eicosanoids, which in turn possess numerous biological activities including modulation of ion transport, control of bronchial and vascular smooth muscle tone, and stimulation of peptide hormone secretion. The genomic ordering of genes and their phylogenetic tree indicate an ongoing expansion in the rodents (Fig. 14b,c). This suggests that adaptive evolution has been involved in diversifying their functions.

6.4 Proteolysis

Protease genes also represent an example of rapid evolution in the rat genome. The rat contains 626 protease genes (~1.7% of the genes), similar to mouse (641) and more than human (561). One hundred and two rat protease genes are not found in human, and 42 are absent from mouse. Several rat gene families have expanded; most are involved in reproductive or immunological functions, and have evolved independently in the rat and mouse lineages.

These gene family expansions dramatically illustrate how large-scale genomic changes have accompanied species-specific innovation. Positive selection of duplicated genes has afforded the rat an enhanced repertoire of precisely those genes that allow reproductive success despite severe competition from both within its own, and with other species. This serves as a general illustration of the importance of chemosensation, detoxification, and proteolysis in innovation and adaptation.

7 Human Disease Gene Orthologs in the Rat Genome

The rat is recognized as the premier model for studying the physiological aspects of

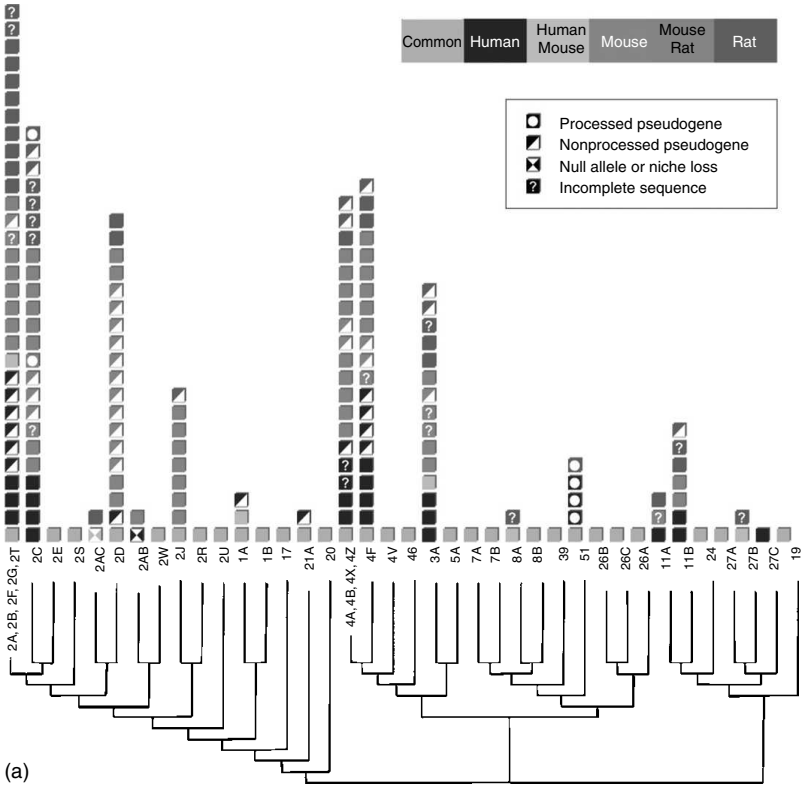

Fig. 14 Evolution of cytochrome P450 (CYP) protein families in rat, mouse, and human. (a) Dendrogram of topology from 234 full-length sequences. The 279 sequences of 300 amino acids; subfamily names and chromosome numbers are shown. Black branches have >70% bootstrap support. Incomplete sequences (they contain Ns) are included in counts of functional genes (84 rat, 87 mouse, and 57 human) and pseudogenes (including fragments not shown; 77 rat, 121 mouse, and 52 human). Thus, 64 rat genes and 12 pseudogenes were in predicted gene sets. Human CYP4F is a null allele due to an in-frame STOP codon in the genome, although a full-length translation exists (SwissProt P98187). Rat CYP27B, missing in the genome, is ''incomplete'' since there is a RefSeq entry (NP_446215). Grouped subfamilies CYP2A, 2B, 2F, 2G, 2T, and CYP4A, 4B, 4X, 4Z, occur in gene clusters; thus nine loci contain multiple functional genes in a species. One (CYP1A) has fewer rat genes than human, seven have more rodent than human, and all nine have different copy numbers. CYP2AC is a rat-specific subfamily (orthologs are pseudogenes). CYP27C has no rodent counterpart. Rodent-specific expansion, rat CYP2J is illustrated below. (b) The neighbor-joining tree, with the single human gene, contains clear mouse (Mm) and rat (Rn) orthologous pairs (bootstrap values >700/1000 trials shown). Bar indicates 0.1 substitutions per site. (c) All rat genes have a single mouse counterpart except for CYP2J 3, which has further expanded in mouse (mouse CYP2J 3a, 3b, and 3c) by two consecutive single duplications. The genes flanking the CYP2J orthologous regions (rat chromosome 5, 126.9–127.3 Mb; mouse chromosome 4, 94.0–94.6 Mb; human chromosome 1, 54.7–54.8 Mb) are hook1 (HOOK1; pink) and nuclear factor I/A (NFIA; cyan). Genes (solid) and gene fragments (dashed boxes) are shown above (forward strand) and below (reverse strand) the horizontal line. No orthology relation could be concluded for most of these cases. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. liii.)

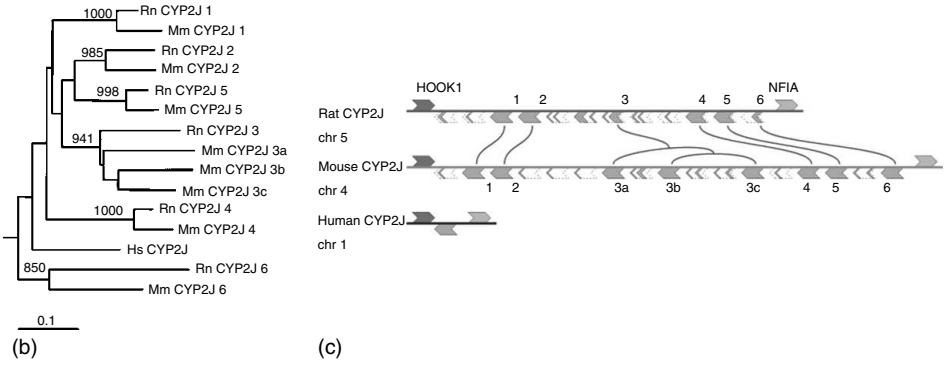

Fig. 14 (*Continued*)

many human diseases, but it has not had as prominent a role in the study of simple genetic disease traits. The rat genome provides an opportunity to use the more than 1000 human Mendelian disorders that have associated loci and alleles to link the rat to human disease examples. The precise identification of the rat orthologs of human genes that are mutated in disease creates further opportunities to discover and develop rat models for biomedical research.

Predicted rat genes were compared with 1112 well-characterized human disease genes that were verified and classified on the basis of pathophysiology. So, 844 (76%) have 1 : 1 orthologs in the rat as predicted by Ensembl. These predictions are likely to be of high quality since 97.4% of the 11 422 rat:human 1 : 1 orthologs predicted by Ensembl were found in orthologous genomic regions.

The proportion of human disease genes with single orthologs in the rat (76%) was higher than the proportion for all human genes (46%). Careful analysis of the remaining 268 human genes not predicted to show 1 : 1 orthology indicated that only six of the human disease genes lack likely rat orthologs among genome, cDNA, EST, and protein sequences. Thus, it appears that, in general, genes involved in human disease are unlikely to have diverged, or to have become duplicated, deleted, or lost as pseudogenes, between rat and human divergence.

Comparisons of K_S, K_A, and the K_A/K_S ratio values of human disease orthologs with those of all remaining ortholog pairs found only the K_S distributions differed significantly indicating that coding regions of human disease genes and their rat counterparts have mutated more rapidly than the nondisease genes. Factors influencing the specific loci could cause this result, or the disease genes may characteristically reside in genomic regions that exhibit higher mutation rates.

The disease gene set was next grouped into 16 disease-system categories and analyzed (Fig. 15). Only five disease systems exhibited significant K_A/K_S differences with respect to the remaining samples. Neurological and malformation-syndrome disease categories manifested K_A/K_S ratios consistent with purifying selection acting on these gene sets. In contrast, the pulmonary, hematological, and immune categories manifested the highest median K_A/K_S ratios, consistent with a role for more positive selection, or reduced selective constraints, among these genes.

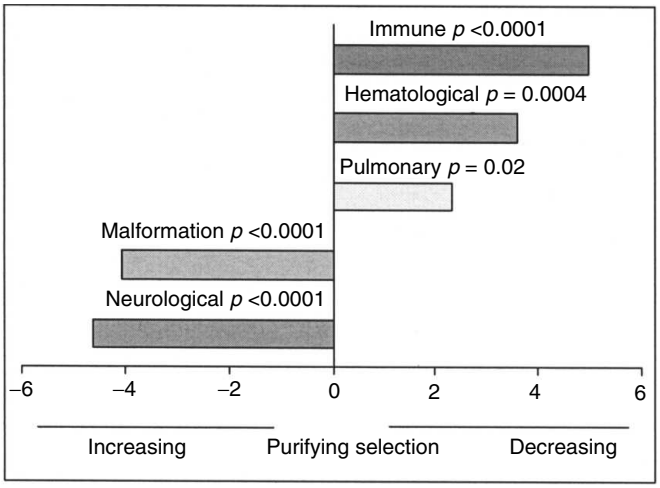

Fig. 15 Selective constraints differ for human disease systems in the rat genome. Human disease-system categories showing significant differences ($p < 0.05$) in a nonparametric test [Mann–Whitney–Wilcoxon] comparing K_A/K_S (human:rat) ratios. *P*-values from two-level tests between genes from one disease system and the remaining genes. (Mean–Mean0)/Std0 values from multilevel tests from sixteen categorized disease systems. Negative values for neurological (−4.63) and malformation-syndrome (−4.04) categories were observed to be consistent with K_A/K_S ranges where purifying selection predominates. Immune, hematological, and pulmonary categories show positive values of 4.98, 3.59, and 2.34, respectively. Used with permission from *Nature* **428**, 493–521 (2004).

Orthologs of more diverse phyla demonstrated consistent results.

These results demonstrate that various disease systems exhibit significantly different average evolutionary rates. The higher rates noted for the immune system disease genes are consistent with rapid diversification of the functions of the immune systems of rodents and humans. This is expected for genes involved in controlling species-restricted infectious agents if strong adaptive pressure acts during host–pathogen coevolution. Thus, results of studies of these rodent genes may be less directly relevant to our understanding of human immune system diseases than results obtained for other pathophysiology disease systems where conservation is greater and purifying selection is stronger.

A number of genes were examined that harbor triplet nucleotide repeats, and are involved in human neurological disorders, such as Huntington disease, a condition caused by CAG triplet repeat expansion producing abnormally long polyglutamine tracts in an otherwise normal protein. Analysis of the rat:human orthologs of these disease genes indicated that repeat length is substantially shorter in all cases in the rat than in the normal human gene (Fig. 16). To date, there are no naturally occurring rat strains described that exhibit neurological disease associated with repeat expansion mechanisms. The rat may lack repeat

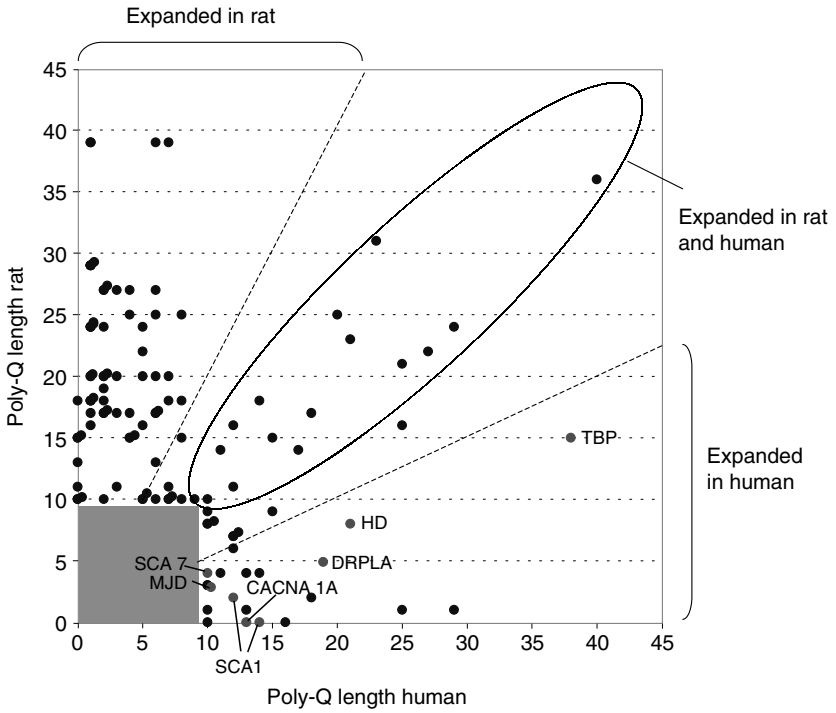

Fig. 16 Polyglutamine repeat length comparison between human and rat. Points represent protein poly-Q length for rat and human. Red points correspond to repeats in genes associated with human disease: SCA1, spinocerebellar ataxia 1 protein, or ataxin1; SCA7, spinocerebellar ataxia 7 protein; MJD, Machado–Joseph disease protein; CACNA1A, spinocerebellar ataxia 6 protein, or calcium channel α-1A subunit isoform 1; DRPLA, dentatorubro–pallidoluysian atrophy protein; HD, Huntington's disease protein, or huntingtin; TBP, TATA binding protein or spinocerebellar ataxia 17 protein. Repeat lengths over 10 were examined; green shading delineates the range not included in the analysis. Also noted are a set that are expanded in rat and human (black circle) and a set where repeats are expanded in the rat. Used with permission from *Nature* **428**, 493–521 (2004). (See color plate p. liv.)

expansion mutational mechanisms or these orthologs may fail to reach a ''critical repeat length'' susceptible to such mutational mechanisms. Other human genes without known disease association also contain glutamine repeats that are much shorter in the rat orthologs, and thus may be susceptible to mutations that arise through repeat expansion mechanisms. In Fig. 16, it may also be observed that a relatively high proportion of repeats are significantly longer in the rat than in their corresponding human ortholog.

In addition to enabling the direct comparison of rat/human disease orthologs, the rat genome sequence itself is an invaluable aid for discovery of other rat genes to study as disease models. First, genes underlying disease phenotypes with simple inheritance that have been mapped to chromosomal regions can be more easily pursued in both species. Indeed, the

rearrangements of conserved segments between the two species have significant value since they tighten the boundaries of the mapped disease regions and reduce the number of genes potentially associated with the disease phenotype. Second, the identification of multiple alleles contributing to quantitative and complex trait differences that are involved in disease processes can be pursued with more accuracy, both in the initial association phases, and in subsequent efforts to detect causative alleles.

8 Summary

As the third mammalian genome to be sequenced, the rat genome has provided both predictable and surprising information about mammalian species. Although clear at the outset that ongoing rat research would benefit from the resource of a genome sequence, there was uncertainty about how many new insights would be found, especially considering the superficial similarities between the rat and the already sequenced mouse. Instead, the results of the sequencing and analysis have generated some deep insights into the evolutionary processes that have given rise to these different species. In addition, the project was invaluable for further developing the methods for the generation and analysis of large genome sequence data sets.

The generation of the rat draft tested the new ''combined approach'' for large genome sequencing. The high quality of the overall attests of this overall strategy and the supporting software, provide a suitable approach to this problem. With a BAC ''skimming'' component in the underlying data set, the assembly recovered a fraction of the genome that was expected, by analogy to the mouse project to be difficult to assemble from pure WGS data. The BAC skimming component also allowed progressive generation of high quality local assemblies that were of use to the rat community as the project developed.

The rat genome data have improved the utility of the rat model enormously. The rat gene content provides a parts list that can be explored with the high degree of confidence and precision that is appropriate for biomedical research. The resources for physical and genetic mapping have also been improved, since the relative position of individual markers is now known with confidence and there are computational resources to bridge the process of genetic association with gene modeling and experimental investigation.

The expected benefit of a third mammalian sequence providing an outgroup by which to discriminate the timing of events that had already been noted between mouse and human was fully realized. Using the three sequences and other partial data sets from additional organisms, it was possible to measure some of the overall faster rate of evolutionary change in the rodent lineage shared by mice and rats, as well as the peculiar acceleration of some aspects of rat-specific evolution. The observation of specific expanded gene families in the rat should provide material for targeted studies for some time.

The sequence of the rat genome represents the beginning of the full analysis of the mammalian genome and its complex evolutionary history. Much of the additional data required to complete this story will be from other genomes, distantly related to rat. Nevertheless, the prospect of a finished rat genome, polymorphism data

from analysis of other rat strains, and targeted cDNA clone collections will provide rat-specific reagents for routine use in research. Together with the ongoing efforts to fully develop methods to genetically manipulate whole rats and provide effective ''gene knockouts'' the current and future rat genome resources will ensure a place for this organism in genomic and biomedical research for some time.

Acknowledgment

This chapter is based largely on the publication of the rat genome sequence by the Rat Genome Sequencing Project Consortium (*Nature* **428**, 493–521 (2004)). We thank E. Eichler, K. Fetchel, R. Hardison, P. Havlak, K. Kalafus, M. Krzywinski, A. Milosavljevic, L. Pachter, P. Pevzner, C. Ponting, K. Roskin, A. Sidow, A. Smit, G. Tessler, and D. Torrents, for the figures. The rat genome-sequencing project was funded primarily by the NHGRI and NHLBI of the NIH.
